The precipitation-strengthened alloys, which are the most numerous, contain aluminum and titanium for the precipitation of a second strengthening phase, the intermetallic $\text{Ni}_3(\text{Al,Ti})$ known as gamma prime (γ') or the intermetallic Ni_3Cb known as gamma double prime (γ''), during heat treatment. One such alloy, Inconel X-750 (15.5% chromium, 7% iron, 2.5% titanium, 1% columbium, 0.7% aluminum, 0.25% copper maximum, and 0.04% carbon), has more than twice a tensile yield strength Inconel 600 at room temperature and nearly three times as much at 760°C. Its 1000 h stress-rupture strength at 760°C is in the range of 138–207 MPa. Still great tensile yield strength at room at elevated temperatures and a 172-MPa stress-rupture strength at 760°C are provided by Inconel 718 (19% chromium, 18.5% iron, 5.1% columbium, 3% molybdenum, 0.9% titanium, 0.5% aluminum, 0.15% copper maximum, 0.08% carbon maximum), a wrought alloy originally that also has been used for castings. Among the strongest alloys in terms of stress-rupture strength is the wrought or cast IN-100 (10% chromium, 15% cobalt, 5.5% aluminum, 4.7% titanium, 3% molybdenum, 1% vanadium, less than 0.6% iron, 0.15% carbon, 0.06% zirconium, 0.015% boron). Investment cast, it provides a 1000 h stress-rupture strength of 517 MPa at 760°C, 255 MPa at 871°C, and 103 MPa at 982°C. Other precipitation-strengthened wrought alloys include Astroloy; D-979; IN 102; Inconel 706 and 751; M 252; Nimonic 80A, 90, 95, 100, 105, 115, and 263; René 41, 95, and 100; Udimet 500, 520, 630, 700, and 710; Unitemp AF2-1DA; and Waspaloy. Other cast alloys, mainly investment-cast, include B-1900; IN-738X; In-792; Inconel 713C; M 252; MAR-M 200, 246, 247, and 421; NX-188; René 77, 80, and 100; Udimet 500, 700, and 710; Waspaloy; and WAZ-20.

A few of the cast alloys, such as MAR-M 200, are used to produce directionally solidified castings, that is, investment castings in which the grain runs only unidirectionally, as long the length of turbine blades. Eliminating transverse grains improves stress-rupture properties and fatigue resistance. Grain-free alloys, or single-crystal alloys, also have been cast, further improving high-temperature creep resistance. Regarding powder-metallurgy techniques, emphasis has been the use of pre-alloy powder made by rapid solidification techniques (RST) and mechanical alloying (MA), a high-energy milling process using attrition mills or special ball mills. Dispersion-strengthened nickel alloys are alloys strengthened by a dispersed oxide phase, such as thoria, which markedly increases strength at very high temperatures but only moderately so at intermediate elevated temperatures, thus limiting applications. TD-nickel, or thoria-dispersed nickel, was the first of such superalloys, and it was subsequently modified with about 20% chromium, TD-NiCr, for greater oxidation resistance. MA 754 and MA 6000E alloys combine dispersion strengthening with yttria and gamma-prime strengthening.

Cobalt-Base Superalloys

Cobalt-base superalloys are for the most part solid-solution alloys, which, when aged, are strengthened by precipitation of carbide or intermetallic phases. Most contain 20%–25% chromium, substantial nickel and tungsten and/or molybdenum, and other elements, such

as iron, columbium, aluminum, or titanium. One of the most well-known, L-605, or Haynes 25, is mainly a wrought alloy, although it is also used for castings. In wrought form, it contains 20% chromium, 15% tungsten, 10% nickel, 3% iron, 1.5% manganese, and 0.1% carbon. At room temperature, it has a tensile yield strength of about 462 MPa, and at 871°C about 241 MPa. Its 1000 h stress-rupture strength at 815°C is 124 MPa. The more recent Haynes 188 (22% chromium, 22% nickel, 14.5% tungsten, 3% iron, 1.5% manganese, 0.9% lanthanum, 0.35% silicon, and 0.1% carbon), which was developed for aircraft-turbine sheet components, provides roughly similar strength and high oxidation resistance to about 1093°C. MP35N (35% nickel, 20 chromium, 10 molybdenum) is a work-hardening alloy used mainly for temperature corrosion-resistant fasteners. Another alloy, S-816, contains equal amounts of chromium and nickel (20% each), equal amounts of molybdenum, tungsten, columbium, and iron (4% each), and 0.38% carbon. Primarily a wrought alloy, although also used for castings, it has a 1000 h stress-rupture strength of 145 MPa at 815°C. Other casting alloys include AiResist 13, 213, and 215; Haynes 21 and 31, the latter also known as X-40; Haynes 151; J-1650; MAR-M 302, 322, 509, and 918; V-36; and WI-52. Their chromium content ranges from 19% (AiResist 215) to 27% (Haynes 21) and some are nickel-free or low in nickel. Most contain substantial amounts of tungsten or tantalum, and various other alloying elements. Among the strongest in terms of 1000 h stress-rupture strength at 815°C are Haynes 21 and 31—290 MPa and 352 MPa, respectively.

Fabrication

Forging and Hot Working

Many of the commercial nickel-base age-hardenable superalloys can be forged or hot-worked with varying degrees of ease. As has been indicated, the top side of the forging temperature range is limited by such considerations as incipient fusion temperature, grain size requirements, tendency for “bursts,” etc., and the lower side by the stiffness and ductility of the alloy. The recommendations of the metal producer should be sought for optimum forging practice for a given alloy.

The hot extrusion process increases the gamut of superalloys compositions that can be hot-worked. By the use of a suitable sheath on the extrusion billet, otherwise unworkable alloys can be reduced to bar by hot extrusion. In some instances, mild steel has been used for a sheath, while in others nickel–chromium alloys such as Nimonic alloy 75 and Inconel alloy 600 have been employed. Some of the very high-speed hot extrusion processes may be of value in a hot-working the more refractory superalloys.

Heat Treatment

The conventional heat-treating equipment and fixtures are generally suitable for nickel alloys, and austenitic stainless steels are also applicable to the nickel-base high-temperature alloys. Nickel-base alloys are more susceptible to sulfur and lead embrittlement than iron-base alloys. It is therefore essential that all foreign material, such as grease, oil, cutting lubricants, marking paints, etc., be removed by suitable solvents, vapor greasing, or other methods, before heat treatment.

When fabricated parts made from thin sheet or strip of age-hardening alloys such as Inconel alloy X-750 must be annealed during and after fabrication, it is desirable, especially in light gauges, to provide a protective atmosphere such as argon or dry hydrogen to lessen the possibility of surface depletion of the age-hardening elements.

This precaution may not be as necessary in heavier sections, since the surface oxidation involves a much smaller proportion of the effective cross section.

It is usually necessary after severe forming, or after welding, to apply a stress relief anneal (above 899°C) to assemblies fabricated from aluminum–titanium age-hardenable nickel-base alloys prior to aging. It is vitally important to heat the structure rapidly through the age-hardening temperature range of 649°C–760°C (which is also the low ductility range) so that stress relief can be achieved before any appreciable aging takes place. This is conveniently done by charging into a furnace at or above the desired annealing temperature. It has been found at times that the efficacy of this procedure has been vitiated in large welded structures by charging onto a cold car, resulting in a slower and nonuniform heating of the fabricated part when run into the hot furnace. Contrary to expectations, little difficulty has been encountered with distortion under the above rapid heating conditions. In fact, distortion of weldments of substantial size has been reported to be less than by conventional slow-heating methods.

Forming

All of the wrought nickel-base alloys available as sheet can be formed successfully into quite complex shapes and loving much plastic flow. The lower-strength Inconel alloy 600 and Nimonic alloy 75 offer few problems. The high-strength age-hardening varieties, processed in the annealed condition, can be subjected to a surprising amount of cold work and deformation, provided sufficient power is available. Explosive forming has also been successfully employed on a number of nickel-base alloys.

Machining

All of the alloys discussed can be machined, the strongest and highest hardener content materials causing the most difficulty. The recommendations of the metal producer should be followed with respect to Altamont condition of heat treatment, type of tool, speed and feed, cutting lubricant, etc. Wrought alloys of quite high hardener content, such as Inconel alloy 700 and Udimet 500, although difficult to handle, can be machined with reasonable facility using high-speed-steel tools of the tungsten–cobalt type, and cemented carbide tools of the tungsten–cobalt and tungsten–tantalum–cobalt type.

Various electroerosion processes have been successfully used on a number of the age-hardened superalloys and, at hardener levels, may be necessary for some operations such as drilling.

Welding

Inconel alloy 600, Nimonic alloy 75, and other nickel-base alloys of the predominantly solid-solution strengthened type offer no serious problems in welding. All of the common resistance and fusion welding processes (except submerged arc) are regularly and successfully employed.

In handling the wrought superalloys age-hardened with gamma prime, it is necessary to observe certain precautions. Material should be welded in the annealed condition to minimize the hazard of cracking in weld or parent metal. If the components to be joined to have been severely worked or deformed they should be stress-relief-annealed before welding by charging into a hot furnace to ensure rapid heating to this stress-relieving temperature. Similarly, weldments should be stress-relieved before attempting to apply the 704°C age-hardening treatment.

Where subassemblies must be joined in the age-hardened condition, the practice of “safe ending” with a compatible nonaging material prior to age hardening can be usefully employed. The final weldments joining the fully age-hardened components are then made on the “safe ends.”

Such new welding processes as “short arc,” electron, and laser beam have come into increasing use and have been helpful in joining some of the very high hardener content alloys.

Brazing

The solid-solution-type chromium-containing alloys, such as Inconel alloy 600, are quite readily brazed, using techniques and brazing filler metals applicable to the austenitic stainless steels. Generally speaking, it is desirable to braze annealed (stress-free) material to avoid embrittlement by the molten braze metal. Where brazing filler metals are employed that melt above the stress-relieving temperature, a prior anneal is usually not needed. As with the stainless steels, dry hydrogen, argon, and helium atmospheres are used successfully; and vacuum brazing is also very successfully employed.

The age-hardened nickel-base alloys containing titanium and aluminum are rather difficult to braze, unless some method of fluxing, solid or gaseous, is used. Alternatively, the common practice is to preplate the areas to be furnace braised with 0.01–0.03 mm of nickel, which prevents the formation of aluminum or titanium oxide films and permits ready wetting by the brazing filler metal.

Silver brazing filler metals can be used for lower-temperature applications. However, since the nickel-base superalloys are usually employed for high-temperature applications, the higher melting point and stronger and more oxidation-resistant brazing filler metals of the Ni–Cr–Si–B type are generally used. The silver–palladium–manganese and palladium–nickel filler metals also provide useful brazing materials for intermediate service temperatures.

Preheat

See *preheating* and *preheat temperature*.

Preheat Current

In resistance welding, an impulse or series of current impulses that occurs prior to and is separated from welding current.

Preheat Temperature

A specified temperature that the base metal must attain in the welding, brazing, soldering, thermal spraying, or cutting area immediately before these operations are performed.

Preheat Time

In resistance welding, a portion of the preweld interval during which preheat current occurs.

Preimpregnated Decorative Foil

Special papers preimpregnated with melamine resin make possible a broad range of molded-in decoration for thermoset plastic products. By far, the leading application to date is the use of melamine-impregnated rayon paper. It is used to decorate about 70% of all melamine dinnerware. Development of new materials

and techniques to shorten the production cycle is extending use of prepreg paper in closures, cutlery handles, and other markets.

Fabrication

The rayon paper is impregnated with resin under closely controlled conditions at the impregnator's plant to provide a foil with precise resin content, even weight and resin distribution, specified penetration, and absorption. The melamine resin is partially cured, then held at a stable.

Preheating (metals)

(1) Any deliberate heating before some further thermal or mechanical treatment. Intended to confer some benefit. It is normally implicit that the preheat temperature will be exceeded during the subsequent process. See also *weldability*. For tool steel, heating to an intermediate temperature immediately before final austenitizing. For some nonferrous alloys, heating to a high temperature for a long time, in order to homogenize the structure before working. (2) In welding and related processes, heating to an intermediate temperature for a short time immediately before welding, brazing, soldering, cutting, or thermal spraying. (3) In powder metallurgy, an early stage in the sintering procedure when, in a continuous furnace, lubricant or binder burn-off occurs without atmosphere protection prior to actual sintering in the protective atmosphere of the high heat chamber.

Preheating (Plastics)

The heating of a polymeric compound before molding or casting to facilitate the operation or reduce the molding cycle.

Preheat Temperature

A specified temperature that the base metal must attain in the welding, brazing, soldering, thermal spraying, or cutting area immediately before these operations are performed.

Preheat Time

In resistance welding, a portion of the preweld interval during which preheat current occurs.

Preimpregnated Decorative Foil

Special papers preimpregnated with melamine resin make possible a broad range of molded-in decoration for thermoset plastic products. By far, the leading application to date is the use of melamine-impregnated rayon paper. It is used to decorate about 70% of all melamine dinnerware. The development of new materials and techniques to shorten the production cycle is extending the use of prepreg paper in closures, cutlery handles, and other markets.

Fabrication

Rayon paper is impregnated with resin under closely controlled conditions at the impregnator's plant to provide a foil with precise resin content, even weight and resin distribution, specified penetration, and absorption. Melamine resin is partially cured, then held at a stable, flexible B-stage, cut into sheets convenient for printing, and shipped to printers for decoration.

Designs are printed by either lithography or silkscreen with special inks and techniques developed by specialty printers. Virtually any

P

design can be reproduced, including photographs in black and white or full color. Even moldable silver and gold inks have been perfected.

The printed foil is cut to final size and shape and delivered to the molder ready for the mold. Normally, the product to be decorated is formed and partially cured; then the mold is opened, the foil inserted, and the mold closed to fuse the foil to the product and complete the cure. Except when metallic inks are used, paper is inserted so that the designs face the product. The foil becomes transparent but forms a protective melamine surface.

Decorating Closures

A relatively new development is the use of prepreg foils to decorate closures such as cosmetic jar covers. Previously, decoration was limited to the one or two colors possible with hot stamping and direct screening or to lithography on metal, which is subject to rust. Molding the foil into a thermosetting plastic closure gives the package designer full color range and combination and later permits the change of design without altering the molds.

The demand of the closure producer for high-volume, high-speed molding encouraged a research program that has yielded a new one-shot decorative foil. Instead of preforming the product and opening the mold for the insertion of the foil, the new one-shot foil is put into the mold first, the molding powder poured on top of it, and the mold closed for a complete, uninterrupted cycle. As yet, the new technique has been used only for closures, but the same principles are believed to be technically feasible for larger products such as dinnerware. More immediate markets for the one-shot foil are control knobs and drawer pulls.

Materials

Prepreg foils can be used to apply decoration to a wide variety of thermosetting resins, including all melamines, all ureas, and most phenolics.

Although the self-effacing rayon foil is most popular for dinnerware and most melamine and urea products, opaque prepreg paper is favored for such products as cutlery handles, clock faces, switch plates, and trays. The opaque paper shields the darker resins and even permits use of the varicolored odds and ends in a molder's inventory for such applications as a clock face. Often, of course, the opaque paper is used to provide a decorative color contrast.

The opaque print-base paper is made with a high-purity alpha pulp, fillers, pigments, and other additives. Like the rayon foils, this paper is preimpregnated with the resin and advanced to a stable B-stage for shipment and printing. Among other products for which the opaque prepreg papers are suitable are handles for pots and pans, organ keys, and wall tile.

Preimpregnated Materials for Reinforced Plastics

The so-called *prepregs* are ready-to-mold reinforced plastics with resin and reinforcement pre-combined into one easy-to-handle material. They are fabricated by what is called dry layup techniques; the alternative is the wet layup method of combining a liquid resin and reinforcement at the mold.

Fabrication

Prepregs are produced by impregnating continuous webs of fabric or fiber with synthetic resins under close control. The resins are

then partially cured to the B-stage, or partly polymerized. At this stage, the preimpregnated material remains stable, and may be shipped or stored, ready for forming into the final shape by heat and pressure.

Most of the controllable variables in a reinforced plastics structure are taken into account in the production of a prepreg, for example, resin type and content, reinforcement, and finish, which are largely determined by the requirements of the final laminate. Prepregs are preengineered to meet performance and processing requirements.

Major Advantages

The major advantages of using preimpregnated materials for molding reinforced plastics products are (1) high and more uniform strength, (2) uniform quality, (3) simplified production, and (4) design freedom.

Key to the majority of the advantages of prepreg is the close control maintained through all stages of the preimpregnated process. For example, the amount of resin solution picked up by the reinforcing web as it passes through one or more resin baths is influenced not only by resin viscosity and resin solids, but also by web tension and speed (which regulate the time the reinforcement is in the bath) and by the temperature of the resin. Because of the high degree of control afforded by preimpregnating equipment over tension, speed, and temperature, resin content can be controlled $\pm 2\%$.

Such control also permits the production of prepregs with a reinforcement content from as high as 85% to as low as 20%. It is the high reinforcement content possible with prepregs that accounts for the high strength of these materials. Further, since the reinforcement is thoroughly saturated during preimpregnation, little air is entrapped in the reinforced plastic material, assuring better quality in the molded part.

Handling characteristics of prepregs can also be closely controlled by controlling the temperature and speed of the material as it passes through the second stage of the process, where resin is partially cured. Temperature of the drying oven, speed of travel, and resin type and content determine the degree of polymerization or B-stage, which, in turn, determines such handling and molding characteristics as resin flow, gel time, tack, and drape. In prepregs, these factors can be tailored to suit a variety of production molding requirements.

Prepregs also facilitate the use of such resins as phenolics, melamines, and silicones, which, when available in liquid form, are usually solvent solutions (except for newer solventless silicones). Wet layup of solvent solutions of resins is usually unsatisfactory, at best, because solvents are released during cure. As B-staged prepregs, such resin systems are virtually solvent-free.

Prepregs can also be made using resins whose viscosities are so low that they would be difficult, or impossible, to handle using wet layup techniques.

Prepregs can be partially advantageous to the smaller reinforced plastics fabricator, eliminating the need for resin formulation; scrap loss can be minimized by chopping up or macerating leftover prepreg to form molding compound.

Because the resin is already properly distributed throughout the reinforcement, prepregs offer distinct advantages in molding odd-shaped parts, with varying thicknesses, undercuts, flanges, etc. They preclude the problem of excessive flow of resin, eliminating resin-rich or resin-starved areas of such parts. Cut to the proper pattern, the prepreg can be accurately prepositioned in the mold to provide optimum finished parts.

Possibly the greatest advantage of prepregs is that they lend themselves to automated, high-production molding. The continuous prepreg web can be prepared for molding by cutting, slitting, or blanking operations. Often parts can be molded directly from such blanks. Die-cut parts can also be used to preassemble a complete lay up in advance of molding, thus minimizing press time.

Materials Used

A wide range of reinforcing materials and resins are available in prepreg form. Principal resins are polyesters, epoxies, phenolics, melamines, silicones, and several elastomers. The most commonly used reinforcements are glass cloth, asbestos, paper, and cotton. Specialty fibrous reinforcements include high-silica glass, nylon, rayon, and graphite.

Reinforcing Materials

Reinforcing materials available in prepregs today include the following:

1. Glass fiber is by far the largest volume reinforcing material in use today. Prepregs incorporating glass fiber are available in the form of preimpregnated roving (for filament winding), cloth, and mat. It provides a good balance of properties: outstanding strength-to-weight characteristics, high tensile strength, high modulus of elasticity compared to other fibers, resilience, and excellent dimensional stability. It is used for such products as airplane and missile parts, ducts, trays, electrical components, truck body panels, and construction materials.
2. Asbestos is used in prepregs in the form of paper, felt, and fabrics. All provide good thermal insulation. Papers provide cost advantage where structural characteristics are not critical. Felts provide maximum tensile and flexural strength and good ablation resistance. Asbestos fabrics are used principally in flat laminates. Prepregs employing asbestos webs have won an important place in rocket and missile components in good part because of their remarkable short-term resistance to extremes of temperature and flame exposure.
3. Paper, a leading reinforcement for high-pressure prepreg laminates, is inexpensive, prints well, and has adequate strength for its principal uses as counter surfacing, furniture and desktops, and wall boards.
4. Specialty reinforcements, like high-silica glass, quartz, graphite, nylon, have their main use in missile and rocket parts. Some exhibit unusual high-temperature resistance; some are good ablative materials.

Resins

The major plastic resins used in prepregs are polyesters, epoxies, phenolics, melamines, and silicones, although any thermosetting resin or elastomer may be used.

1. Polyester resin prepregs are comparatively low in cost and easy to mold at low temperatures. They have good mechanical, chemical, and electrical properties, and some types are flame resistant.
2. Epoxy prepregs provide high mechanical strength, excellent dimensional stability, corrosion resistance and

interlaminar bond strength, good electrical properties, and very low water absorption.

3. Phenolic prepregs have high mechanical strength, excellent resistance to high temperature, good thermal insulation and electrical properties, and high chemical resistance.
4. Melamine prepregs have excellent color range and color retention, high abrasion resistance, good electrical properties, and are resistant to alkalis, and flame.
5. Silicone prepregs provide the highest electrical properties available in reinforced plastic and are the most heat stable. They retain strength and electrical characteristics under long-term exposure to 260°C–316°C.

Actually any thermosetting resin or elastomer may be used and any continuous-length reinforcement. Even sheet material not capable of supporting its own impregnated weight in a drying oven can be used. The web may be a woven fabric, nonwoven sheet, or continuous strand or roving. After impregnation, the prepreg may be slit into a tape, chopped, macerated, or cut to a specified pattern, depending on the requirements of the part and the desire of the molders.

Molding

The one requirement for using prepregs is that some heat and pressure must be used to mold them to a final shape. They cannot be room-temperature cured. Prepregs can be formulated to fit all other methods of processing; the four major methods are vacuum-bag molding, pressure-bag molding, matched metal-die molding, and filament and tape winding.

The choice of method of forming prepregs is most often governed by production volume. The exception is the critical part, like a missile component, where the higher performance qualities achieved by matched metal-die molding justifies the use of this process even for a few hundred parts.

The vacuum-bag molding method uses the simplest and most economical molds and equipment and is used where the number of parts needed is low or where frequent design changes occur.

The pressure-bag method of molding uses pressures up to 0.70 MPa to achieve greater strength than is possible with the vacuum-bag method. Mold and equipment costs remain comparatively low. In both vacuum-bag and pressure-bag molding, additional pressure with resulting higher strengths can be achieved through the use of an autoclave.

Matched metal-die molding is used for long runs where it gives the lowest cost and the highest production rates. This method permits an accurate control of dimensions, density, rate of cure, and surface smoothness.

Tape and filament winding are used for cylindrical, spherical, and conical shapes and can produce high physical properties and high strength-to-weight characteristics. Techniques range from simple winding to highly automated operations. In fact, it comes closest to automation of current fabrication methods and achieves homogeneous, void-free products. It does not involve the expense of matched metal dies.

Preimpregnation (Reinforced Plastics)

The practice of mixing resin and reinforcement and effecting partial cure before use or shipment to the user. See also *prepreg*.

P

Preload/Prestress

The tightening load and resultant stress applied to threaded fasteners, such as bolts, screws and studs, which clamp components together. A high level of preload maintains pressure tightness, largely eliminates the risk of fastener fatigue, reduces the risk of the fastener becoming unscrewed because of vibration, and, in structural steel work, ensures that the load between members is carried by interfacial friction rather than by shear loading of the fastener. Usually, maximum mechanical and economic efficiency are achieved when the specified prestress matches the materials yield stress. However, in practice, tightening equipment and techniques are of limited precision, and hence, prestress is commonly specified as about 80% of yield stress to avoid the risk of gross yielding leading to necking and failure. An alternative approach, in special cases, is to develop a technique that deliberately extends the fastener beyond yield by a controlled amount without causing necking. Fasteners operating in their creep range are usually tightened to lower levels of prestress selected for the particular application. At first consideration, it might be thought that the preload is directly additive to service loads applied to the assembly, for example, by the internal pressure acting on a pipe flange. However, this is not usually the case, and, generalizing, only a small proportion of the service load is additive to the preload. This is a consequence of the small cross-sectional area of the fastener relative to the much larger load-bearing area of the flange and the associated differences in elastic strain. As a result, until such time as the service stress nearly matches the prestress, the joint will remain pressure tight. It follows that large fluctuations in service stresses will induce only small fluctuations in the fastener stress, so fatigue will be avoided provided the service stress does not closely approach the prestress. Some control of preload is provided automatically by proportioning wrench size to fastener diameter, but many other techniques are available for measuring preload. These include the torque wrench, mechanical or ultrasonic measurement of fastener extension, measurement of turn of nut angle after an initial “nip” has been achieved, and the observation of deformable washers or collapsible projections on nut faces. All have their respective advantages and problems.

Premimn

Material or treatment better than the normal standard, or the additional price for such material or treatment.

Premix (Metals)

(1) A uniform mixture of components prepared by a metal powder producer for direct use in compacting. (2) A term sometimes applied to the preparation of a premix; see preferred term *mixing*.

Premix (Plastics)

A plastic molding compound prepared prior to and apart from the molding operations and containing all components required for molding: resin, reinforcement, fillers, catalysts, release agents, and other ingredients.

Premix Burner

A burner used in flame emission and atomic absorption spectroscopy in which the fuel gas is mixed with the oxidizing gas before reaching the combustion zone. See the term *nebulizer*.

Premix Moldings

Premix molding materials are physical mixtures of a reactive thermosetting resin (usually polyester), chopped fibrous reinforcement (usually fibrous glass, asbestos, or sisal), and powdered fillers (usually carbonates or clays). Such mixtures, when properly formulated, can exhibit a wide range of performance properties at variable costs. In general, the resin type will determine the corrosion-resistance properties of the premix; increasing amounts of glass reinforcement will increase strength and increasing amounts of filler will reduce costs and corrosion resistance.

Comparative Benefits

In comparison with such corrosion-resistant metals as brass, bronze, and stainless steels, premixes offer, primarily, cost reductions due to the ease of manufacture of complex shapes, and reductions in actual material costs. In some cases, design latitude, colorability, resistance to abrasion, and reduction in weight are also important factors in favor of the premix parts.

In comparison with aluminum, premixes can offer superior corrosion resistance, especially to alkaline detergents, in addition to the advantages noted earlier.

In comparison with thermoplastic resins, premix materials offer considerably greater hardness, rigidity, and heat resistance. Premix materials are also stronger. Thermoplastics usually have superior colorability, surface smoothness, gloss, and a broader range of corrosion resistance. Thermoplastics are also somewhat lower in cost for the molded item when the number of parts is large. In general, tooling costs for injection-molded thermoplastics are higher, but molding, material-handling, and finishing costs are lower for thermoplastics.

Phenolics, ureas, and melamines are considerably less strong than glass fiber-reinforced premixes, and, in general, they do not have as good a range of resistances to aqueous solutions as do properly formulated premixes. Phenolics, of course, also have limited color possibilities.

In comparison with most other plastics, premixes are usually more difficult to handle because they are more difficult to meter or preweigh automatically. Generally, they must be preweighed by hand to an exact mold charge. Recently, however, there has been a trend toward extrusion and chopping of premix to logs of predetermined charge weight.

Molding

Because premixes are essentially heterogeneous materials, certain well-known molding phenomena such as weld lines and orientation during flow take on added significance. Fiber orientation tends to give somewhat greater effects of anisotropy, and more care must be taken with premix molded parts to prevent excessive orientation. Similarly, weld lines in premix parts tend to be proportionately weaker than weld lines in thermoplastics. Much of the “art” of premix molding is concerned with reducing or eliminating orientation and weld line effects by proper mold design, molding conditions (closing speed, pressure, temperature), and by selection of charge shape and location in the mold. Again, recent advances in glass fiber manufacturing have resulted in superior glass fibers, which reduce orientation and weld-line effects.

Premixes are generally molded in conventional compression molds and presses using pressures on the order of 3.5–13.6 MPa and temperatures in the range of 121–177°C.

Premixes are also occasionally molded in transfer presses, usually at somewhat higher pressures. Transfer molding tends to reduce strength properties by degrading the glass fibers in the compounds.

Premixes are suitable for molding very complex shapes over a wide range of sizes. Filter plates and frames weighing over 45.4 kg have been molded successfully.

A large volume of premix is consumed in automotive air-conditioner and heater housings and ducts. These parts are low-cost, low-strength items requiring high rigidity and good heat resistance. Other large-volume applications include electrical insulators and housings of various types. Most premixes are manufactured captive; that is, molders prepare their own premix material. The advantages of captive premix are lower initial raw material costs, reduced packaging costs, ability to formulate faster curing compounds, and ability to tailor-make special compounds for each part. The major disadvantage of the premix very often is lack of good quality control. Another disadvantage of the captive operation is that not enough compound development effort is spent in working out the “bugs” in a new formulation before such a formulation becomes commercial.

Compounding

Premixes are prepared by mixing glass, filler, and resin mix in a 180° spiral double-arm dough mixer. Blade clearance should be about 6.4–12.7 mm. The resin mix is usually prepared separately and includes resident, lubricant, catalyst, inhibitor, and other minor additives. The resin mix is charged to the mixer, followed by the filler. After the filler is thoroughly blended (usually 10 min is required) the fibrous material can be added. If the fibrous material is glass, care must be taken to disperse the fiber to prevent clumping; close control of mixing time must be maintained to prevent fiber breakdown. Recently, a high strand integrity fiber has been introduced, which reduces fiber-breakdown tendency.

After mixing, the premix must be stored in airtight containers to prevent styrene monomer loss. Cellophane bags may be used to store small amounts of premix (6.7–9 kg), and larger bins or hoppers may be used for larger quantities.

Premix of high filler loadings may be extruded through screw-type or ram-type extruders and automatically chopped to logs of predetermined weight.

The storage life of premix that is sealed against styrene loss may vary from 1 or 2 days to 1 year depending upon formulation. The premix with short storage life can be molded at lower temperatures and shorter cycles than the more stable premix.

Premolding

In composites fabrication, the *layup* and partial *cure* at an immediate cure temperature of a laminated or chopped fiber detail part to stabilize its configuration for handling and assembly with other parts for final cure.

Prep.

Preparation (of weld).

Preparation as in Joint Preparation or Weld Preparation

(1) The various activities involved in preparing a joint for welding or the geometry and dimensions of the surfaces to be welded.

Preplasticization

Technique of premelting injection molding plastic powders in a separate chamber, then transferring the melt to the injection chamber. See also *injection molding* (plastics).

Preply

A composite material *lamina* in the raw material stage, ready to be fabricated into a finished *laminate*. The lamina is usually combined with other raw laminae before fabrication. A prepoly encloses a fiber system that is placed in position relative to all or part of the required matrix material to constitute the finished lamina. An organic matrix prepoly is called a *pregreg*.

Prepolymer

A chemical intermediate with a molecular weight between that of the *monomer* or monomers and the final *polymer* or resin.

Prepolymer Molding

In the urethane foam field, a system in which a portion of the *polyol* is pre-reacted with the isocyanate to form a liquid *prepolymer* with a viscosity range suitable for pumping or metering. This component is supplied to end users with a second premixed blend of additional polyol, catalyst, blowing agent, and so forth. When the two components are subsequently mixed, foaming occurs. See also *one-shot molding*.

Prepreg

In composites fabrication, either ready-to-mold material in sheet form or ready-to-wind material in *roving* form, which may be cloth, mat, unidirectional fiber, or paper, impregnated with resin and stored for use. The resin is partially cured to a *B-stage* and supplied to the fabricator, who lays up the finished shape and completes the cure with heat and pressure. The two distinct types of prepreg available are commercial prepregs, in which the roving is coated with a hot melt or solvent system to produce a specific product to meet specific customer requirements; and wet prepreg, in which the basic resin is installed without solvents or preservatives but has limited room temperature shelf life.

Preproduction Test

A test or series of tests conducted by an adhesive manufacturer to determine conformity of an adhesive batch to established production standards, or by a fabricator to determine the quality of an adhesive before parts are produced, or by an adhesive specification custodian to determine conformance of an adhesive to the requirements of a specification not requiring qualification test. Compare with *acceptance test* and *qualification test*.

Preservatives

Chemicals used to prevent oxidation, fermentation, or other deterioration of foodstuffs. The antioxidants, inhibitors, and stabilizers used to retard deterioration of industrial chemicals are not usually called preservatives. The most usual function of a preservative is to kill bacteria, and this may be accomplished by an acid, an alcohol, an aldehyde, or a salt. A legal requirement under the Food and

P

Drug Act is that a preservative be nontoxic in the quantities permitted. **Sugar** is the most commonly used preservative for fruit products. **Sodium chloride** is used for protein foods. **Sodium nitrate** is reduced as sodium nitrite in curing meats, and the nitrite as an inhibitory action on bacterial growth, the effect being greatest in acid flesh. **Potassium sorbate**, a white, water-soluble powder, inhibits the growth of many molds, yeasts, and bacteria which cause food deterioration, and it is used in cheese, syrups, pickles, and other prepared foods.

The inhibitory effect of organic acids is due chiefly to the undissociated molecule. **Acetic acid** is normally more toxic to bacteria than lactic acid, but when sugar is present, the reverse is true, and citric acid then has little toxicity. The inhibitory action of inorganic acids is due mainly to the pH change that they produce.

Only small quantities of chemicals are usually needed for preservation. Preservatives are also marketed for external application to foodstuffs in storage, though these are more properly classified as fumigants. Beverages containing fruit juices or little carbonation are preserved with less than 0.05% **sodium benzoate**. Methyl, propyl, butyl, and ethyl **parabens**; **potassium sorbate**; **sodium dihydroacetate**; and **imidazolidinyl urea** are all industrial **microbials** used in the food, cosmetic, and pharmaceutical industries.

Preshadowed Replica

A replica for fractographic or metallographic inspection that is formed by the application of shadowing material to the surface to be replicated. It is formed before the thin replica film is cast or otherwise deposited on the surface. See also *shadowing*.

Presintered Blank

A metal powder compact sintered at a low temperature but at a long enough time to make it sufficiently strong for metal working. See also *presintering*.

Presintered Density

The relative density of a presintered compact. See also *presintering*.

Press

A machine tool having a stationary bed and a slide or ram that has reciprocating motion at right angles to the bed surface, the slide being guided in the frame of the machine. See also *hydraulic press*, *mechanical press*, *slide*, and *straight-side press*.

Press Brake

An open-frame single-action press used to bend, blank, corrugate, curl, notch, perforate, pierce, or punch sheet metal or plate. See also the term *mechanical press brake*.

Press-Brake Forming

A metal forming process in which the workpiece is placed over an open die and pressed down into the die by a punch that is actuated by the ram portion of a *press brake*. The process is most widely used for the forming of relatively long, narrow parts that are not adaptable

to *press forming* and for applications in which production quantities are too small to warrant the tooling cost for contour *roll forming*.

Pressed Capacity

The rated force a *press* is designed to exert at a predetermined distance above the bottom of the stroke of the *slide*.

Press Clave

In composites fabrication, a simulated autoclave made by using the platens of a press to seal the ends of an open chamber, providing both the force required to prevent loss of the pressurizing medium and the heat required to cure the laminate inside.

Pressed Bar

(1) A powder metallurgy compact in the form of a bar. (2) A green (unsintered) rectangular compact.

Pressed Density

The weight per unit volume of an unsintered compact. Same as green density.

Press Fit

An interference or *force fit* made through the use of a press. See *interference fit*.

Press Forging

(1) The forging of metal between dies by mechanical or hydraulic pressure; usually accompanied with a single work stroke of the press for each die station. (2) This achieves a more uniform deformation throughout the section compared with drop forging.

Press Forming

Any sheet metal forming operation performed with tooling by means of a mechanical or hydraulic press.

Pressing

(1) In metal working, the product or process of shallow drawing of sheet or plate. (2) Forming a powder metallurgy part with compressive force. See also *compacting*.

Pressing Area

The clear distance (left to right) between housings, stops, gib-ways, or shoulders of strain rods, multiplied by the total distance from front to back on the bed of a metal forming *press*. Sometimes called working area.

Pressing Crack

A rupture in a green powder metallurgy compact that develops during ejection of the compact from the die. Sometimes referred to as a slip crack.

Pressing Skin

The surface of a powder metallurgy compact that is superficially more deformed than the interior due to a preferential alignment of the particles caused by contact with the die wall and punch faces.

Press Load

The amount of force exerted in a given forging or forming operation.

Press Quenching

A quench in which hot dies are pressed and aligned with a part before the quenching process begins. Then the part is placed in contact with a quenching medium in a controlled manner. This process avoids part distortion.

Press Slide

See *slide*.

Press Tool

The complete tool assembly used for forming powder metallurgy compacts that consists of the die, a die adapter, the punches, and, when required, a core rod.

Pressure Bag Molding

A process for molding reinforced plastics in which a tailored, flexible bag is placed over the contact lay-up on the mold, sealed and clamped in place. Fluid pressure, usually provided by compressed air or water, is placed against the bag, and the part is cured. See also *vacuum bag molding*.

Pressure Break

In laminated plastics, a break in one or more outer sheets of the paper, fabric, or other base, which is visible through the surface layer of resin that covers it.

Pressure Bubble Plug-Assist Forming

A *thermoforming* process in which a heated plastic sheet is positioned over the mold and air is blown up through the base plate channel causing the sheet to billow upward. The plug assist pushes the sheet into the mold cavity and vacuum is applied to transfer the sheet from the plug to the mold surface.

Pressure Casting

(1) Making castings with pressure on the molten or plastic metal, as in *injection molding*, *die casting*, *centrifugal casting*, cold chamber pressure casting, and *squeeze casting*. (2) A casting made with pressure applied to the molten or plastic metal. (3) Casting processes in which the molten metal is injected under pressure into reusable metal molds. The process offers dimensional accuracy, good surface detail, and finish with a fine grain size and minimum porosity. It is suitable for low melting point alloys, particularly those of zinc

and aluminum, having relatively low shrinkage during solidification. Pressures can be as high as 10,000 psi (670 bars).

Pressure-Controlled Welding

A resistance welding process variation in which a number of spot or projection welds are made with several electrodes functioning progressively under the control of a pressure-sequencing device.

Pressure Gas Welding

An oxyfuel gas welding process that produces coalescence simultaneously over the entire area of abutting surfaces by heating them with gas flames obtained from the combustion of a fuel gas with oxygen and by application of pressure, without the use of filler metal.

Pressure-Impregnation-Carbonization (PIC)

A densification process for carbon-carbon composites involving pitch impregnation and carbonization under high temperature and isostatic pressure conditions. This process is carried out in hot isostatic pressing equipment. See also *carbon-carbon composites*.

Pressure Intensifier

In composites fabrication, a layer of flexible material (usually a high-temperature rubber) used to ensure the application of sufficient pressure to a location, such as a radius, in a lay-up being cured.

Pressureless Sintering

Sintering of loose powder.

Pressure Lubrication

A system of lubrication in which the lubricant is supplied to a bearing under pressure.

Pressure Plate

A plate located beneath the *bolster plate* and a metal forming *press* that acts against the resistance of a group of cylinders mounted to the pressure plate to provide uniform pressure throughout the press stroke when the press is symmetrically loaded.

Pressure-Sensitive Adhesives

Advanced pressure-sensitive adhesives (PSAs) are finding their way into every aspect of modern automobile manufacturing. Automakers and their suppliers are turning to new assembly methods to speed manufacturing, improve quality, lower costs, and meet more stringent environmental regulations. Automotive applications for today's adhesives include mirrors, brakes, headliners, flexible circuit bonding, sound deadening, carpets, door panels, instrument panels, seats, and windows. In a remarkable example of the potential of automotive applications, advanced structural adhesives have even replaced certain chassis-to-body panel welds in new automobiles.

Automotive air bags are yet another component where PSAs play a critical role. In fact, today's air bags are operating more reliably and safely, thanks, in part, to the use of the latest adhesive formulations.

P

The millions of air bags in service today must resist years of shock, vibration, temperature fluctuations, and humidity extremes and then work flawlessly when needed.

Various adhesives are used to assemble and seal the components of air bags, initiators, igniters, gaskets, O-rings, high pressure seals, and vibration dampers.

In general, the adhesives serve to

- Position and set the air bag in place
- Hermetically seal the propellant so that it remains protected from moisture
- Attach the propellant cover, which limits the chance of the ignition during a vehicle fire or other non-impact event

Assembly Benefits

Although acrylic and heat-activated adhesives offer excellent benefits in other applications, the advantages of silicone PSAs increasingly make them the adhesive system of choice for air bag inflators. Manufacturers' testing and field operation indicate that for air bag inflators, silicone PSAs offer numerous advantages over acrylic and heat-activated adhesives. Silicone PSAs simply provide the best seal for air bag inflators. In this application, silicone PSA benefits also include

- Thermal stability not found with acrylic or heat-activated adhesives
- Uniform wet-out and adhesion
- Noncombustibility
- Lower outgassing
- Fewer seal leaks

PSA technology lends itself to manual, semiautomatic, and fully automated manufacturing. Environmental releases of volatile organic compounds are also lower with the new adhesives, good for both worker safety and air quality.

Many manufacturers find that utilizing PSAs in place of heat-activated adhesives saves them money. That is because when using silicone, the reject rate due to leaks, adhesive voids, high outgassing, and other manufacturing problems are also dramatically lower. Postassembly testing shows a 15-fold decline in rejects after postassembly testing.

Added together, the cost factor of utilizing silicone PSAs (not to mention the performance benefits) makes them an attractive option for this application.

Other PSAs

Polymers used in the preparation of PSAs can be divided into two general classes of raw materials. In the first class are polymers that undergo chemical cross-linking following coating to achieve high cohesive strength. Examples include solvent-based acrylic PSAs and solvent-based natural rubber PSAs. Polymers in the second general class do not undergo chemical cross-linking, but instead have high molecular weight (e.g., water-based acrylic, SBR) or physical cross-links (e.g., hot melt styrenic block copolymers) to achieve adequate cohesive strengths.

Pressure Sintering

A hot pressing technique that usually employs low loads, high sintering temperatures, continuous or discontinuous sintering, and simple molds

to contain the powder. Although the terms *pressure sintering* and *hot pressing* are used interchangeably, distinct differences exist between the two processes. In pressure sintering, the emphasis is on thermal processing; in hot pressing, applied pressure is the main process variable.

Pressure-Viscosity Coefficient

The slope of a graph showing variation in the logarithm of viscosity with pressure. The use of the term pressure-viscosity coefficient assumes a linear relationship.

Pressure Welding

Any welding process in which the joint is affected primarily by the interfacial force between components. The effects of the force include disruption of surface films, exposure of clean material, plastic deformation, and mechanical mixing. Heating may be involved but little or no fused metal is incorporated in the joint. Examples include *electrical resistance spot welding* and *flash butt welding*. See preferred terms *cold welding*, *diffusion welding*, *forge welding*, *hot pressure welding*, *pressure gas welding*, and *solid-state welding*.

Pressurized Gas Lubrication

A system of lubrication in which a gaseous lubricant is supplied under sufficient external pressure to separate the opposing surfaces by a gas film.

Prestress

See *preload*.

Prestressed/Pretensioned Concrete

Concrete containing steel bars that are held under tension while the concrete is setting. The tension bars develop a compressive stress in the concrete improving its load carrying capacity.

Pretinning

See preferred term *precoating*.

Prevailing Torque Fasteners

Threaded fasteners that do not rely solely on the preload to prevent loosening. Systems include local thread deformation, non-matching of mating threads forms, nonmetallic inserts, or high friction coatings. See also *lock nuts*.

Preweld Interval

In resistance welding, the time elapsing between the end of squeeze time and the beginning of welding current in making spot welds and in projection or upset welding. In flash welding, it is the time during which the material is preheated.

Primary Alloy

An alloy whose major constituent has been refined directly from ore, not recycled scrap metal. Compare with *secondary alloy*.

Primary Alpha

Alpha phase is a titanium alloy crystallographic structure that is retained from the last high-temperature α - β working or heat treatment. The morphology of α is influenced by the prior thermo-mechanical history.

Primary Creep

The first, or initial, stage of *creep*, or time-dependent deformation. See also the term *creep*.

Primary Crystals

The first type of crystals that separate from a melt during solidification.

Primary Current Distribution

The current distribution in an *electrolytic cell* that is free of *polarization*.

Primary Extinction

In x-ray diffraction, a decrease in intensity of a diffracted x-ray beam caused by perfection of crystal structure extending over such a distance (approximately 1 μm or greater) that interference between multiple reflected beams inside the crystal decreases the intensity of the externally diffracted beam.

Primary Gas

In thermal spraying, the gas constituting the major constituent of the arc gas fed to the gun to produce the plasma.

Primary Leakage

In seals, the leakage of a mechanical seal, with the fluid escaping from the region between the end faces of the primary sealing elements.

Primary Metal

Metal extracted from minerals or ore, or other natural source and free of reclaimed metal scrap. Compare with *secondary metal* and *native metal*.

Primary Mill

A mill for rolling ingots or the rolled products of ingots to blooms, billets, or slabs. This type of mill is often called a *blooming mill* and sometimes called a cogging mill.

Primary Nucleation

The mechanism by which crystallization is initiated in plastics, often by an added nucleation agent.

Primary Passive Potential (Passivation Potential)

The potential corresponding to the maximum active current density (critical anodic current density) of an electrode that exhibits active-passive corrosion behavior.

Primary Recrystallization

A process by which nucleation and growth of a new generation of strain-free grains occur in a matrix that has been plastically deformed. See also *secondary recrystallization*.

Primary Solid Solution

See *solid solution*.

Primary Stress

A directly applied tension or compression stress as opposed to secondary tensile stresses resulting from bending or torsion.

Primary X-Ray

The emergent beam from the x-ray source.

Primer

A coating applied to a surface, prior to the application of an adhesive to improve the performance of the bond. The coating can be a low-viscosity fluid that is typically a 10% solution of the adhesive in an organic solvent, which can wet out the adherend surface to leave a coating over which the adhesive can readily flow. See also the term *adhesive bonding*.

A surfacing material employed in painting or finishing to provide an anchorage or adhesion of the finishing material. A primer may be colorless, or it may have color. In the latter case, it is sometimes called an **undercoat**. A primer is distinct from the filler coat used on woods to fill the pores and thus economize on the more expensive finish. Primers for industrial or production finishing are of two types: air-dry and baking. The air-dry types have drying-oil vehicle bases and are usually called **paints**. They may be modified with resins. They are not used as extensively as the baking-type primers, which have resin or varnish vehicle basis. These dry chiefly by polymerization. Some primers, known as **flash primers**, are applied by spraying and dry by solvent evaporation within 10 min. In practically all primers, the pigments in part most of the anti-corrosion properties to the primer and, along with the vehicle, determine its compatibility with and adherence to the base metal.

Primer coats of **red lead paint** were formally much used on construction steel to give corrosion resistance, but chromate or phosphate primers are now more common. **Barium potassium chromate**, which gives a pale yellow coating, has good anticorrosion properties for steel, aluminum, and magnesium. Zinc yellow paints may also be used as primer coats on metal. **Zinc chromate** is used as a primer on steel. It dissolves when moisture penetrates the paint, and the dissolved chromate retards the corrosion of the steel. **Zinc phosphate primers** applied to iron and steel give corrosion resistance and improve paint adhesion. **Manganese phosphate** forms a dense, crystalline coating on steel, which acts as a corrosion-resistant base for paint. A mixture of 95% zinc powder and 5% of epoxy resin binder in a solvent gives a gray, metallic finish, and the zinc blocks corrosion by galvanic action. In addition to the pigment, various corrosion inhibitors may be used in primer paints. **Ammonium ferrous phosphate** has a platelike structure, which gives impermeability to the film as well as adds corrosion resistance. It is greenish. A primer is especially required in the finishing of sheet-metal objects that are likely to receive dents or severe service, but it is not usually necessary for castings or roughened surfaces.

P

For sheet-metal work, baked enamels were formally much used for the primers for lacquer finishes, but synthetic resin primers give good adhesion and are less expensive.

High-performance solvent- or waterborne epoxy primers with chromate corrosion inhibitors have traditionally protected U.S. Navy aircraft aluminum components from the corrosive effects of seawater and high humidity. With chromates implicated as carcinogenic, nontoxic inhibitors have been sought. Thus far, inorganic nonchromated solutions based on permanganate, cobalamine, and ceric ion as the active corrosion-inhibiting agent have proved only marginally comparable at best in corrosion resistance and paint adhesion. The Navy-developed **Chromium III pretreatment** (SJS6-7) has demonstrated comparable corrosion resistance and paint adhesion in laboratory tests. And **sol-gel formulations** of organic or inorganic polymers, based on the hydrolysis and condensation of metal alkoxides, show promise. Other alternatives are special aliphatic polyurethane topcoats; SJS12, a lead- and chromium-free, high-solids **polyurethane self-priming topcoat** (SPT); and a waterborne polyurethane topcoat.

Waterborne epoxy-based **BR6747 primer**, from Cytec Engineered Materials, matches the long-term corrosion-inhibiting performance of its solvent-based counterpart, **BR127 primer**.

Primes

Metal products, principally sheet and plate, over the highest quality and free from blemishes or other visible imperfections.

Principal Stress (Normal)

The maximum or minimum value of the *normal stress* at a point in a plane considered with respect to all possible orientations of the considered plane. On such principal planes, the shear stress is zero. There are three principal stresses on three mutually perpendicular planes. The state of stress at a point may be (1) uniaxial, a state of stress in which two of the three principal stresses are zero, (2) biaxial, a state of stress in which only one of the three principal stresses is zero, and (3) triaxial, a state of stress in which none of the principal stresses is zero. Multiaxial stress refers to either biaxial or triaxial stress.

Printed Circuit

An electronic circuit produced by printing an electrically conductive pattern, wiring, or components on a supporting dielectric substrate, which may be either rigid or flexible.

Printing

A metallographic method in which a carrier material is saturated with an etchant and pressed against the surface of the specimen. The etchant reacts with one of the phases, and substances form that react with the carrier material, leaving behind a life-size image. Used for exposing particular elements—for example, sulfur (sulfur prints).

Prior Austenite Grain Boundary

The locations, in the phase now existing, of the grain boundaries of the austenite that existed previously.

Prism

A transparent optical element whose entrance and exit apertures are polished plane faces. Using refraction and/or internal reflection, prisms are used to change the direction of propagation of monochromatic light and to disperse polychromatic light into its component wavelengths.

Prismatic Plane

In noncubic crystals, any plane that is parallel to the principal axis (*c* axis).

Probe Analyzer

An analytical facility on an electron microscope.

Probe Ion

In materials characterization, an ionic species intentionally produced by an ion source and directed onto the specimen surface at a known incident angle and a known energy.

Process Annealing

(1) A heat treatment used to soften metal for further cold working. In ferrous sheet and wire industries, heating to a temperature close to but below the lower limit of the transformation range and subsequently cooling for working. In the nonferrous industries, heating above the recrystallization temperatures at a time and temperature sufficient to permit the desired subsequent cold working. (2) Same as sub-critical annealing of steel. It is so called because it is often applied part way through processing when work hardened steel requires softening with minimum scaling.

Processing Window

In forming of plastics, the range of processing conditions, such as stock (melt) temperature, pressure, shear rate, and so on, within which a particular grade of plastic can be fabricated with optimum or acceptable properties by a particular fabrication process, such as extrusion, injection molding, sheet molding, and so forth. The processing window for a particular plastic can vary significantly with design of the part and the mold, with the fabricating machinery used, and with the severity of the end-use stresses.

Process Metallurgy

The science and technology of winning metals from their ores and purifying metals; sometimes referred to as chemical metallurgy. Its two chief branches are *extractive metallurgy* and *refining* and may be extended to include secondary manufacturing processes such as working and heat treatment.

Process Scrap

See *scrap*.

Process Tolerance

The dimensional variations of a part characteristic of a specific process, once the setup is made.

Proeutectoid Carbide

Primary crystals of cementite formed directly in ferrous alloys from the decomposition of *austenite* exclusive of that cementite resulting from the eutectoid reaction. See also *eutectoid*.

Proeutectoid Ferrite

Primary crystals of *ferrite* formed directly in ferrous alloys from the decomposition of *austenite* exclusive of that ferrite resulting from the eutectoid reaction. See also *eutectoid*.

Proeutectoid Phase

Particles of a phase in ferrous alloys that precipitate during cooling after austenitizing but before the eutectoid transformation takes place. See also *eutectoid*.

Profile (Contour) Rolling

In ring rolling, a process used to produce seamless rolled rings with a predesigned shape on the outside or the inside diameter, requiring less volume of material and less machining to produce finished parts.

Profile Examination

(1) The examination of a component in profile, that is, in silhouette (2) The examination of a surface illuminated by a beam of light impinging at a shallow angle so that the shadows magnify surface irregularities.

Profile Gauge

A device comprising a large number of needles arranged in-plane like the teeth of a comb but held in a spine through which they can slide when pressed firmly. The edge formed by the needle tips is pressed against the surface of interest so that the needles slide to record the profile.

Profiling

Any operation that produces an irregular contour on a workpiece, for which a tracer or template-controlled duplicating equipment usually is employed.

Progression

In metal-forming equipment, the constant dimension between adjacent stations in a progressive die.

Progressive Aging

Aging by increasing the temperature in steps or continuously during the aging cycle. See also *aging* and compare with *interrupted aging* and *step aging*.

Progressive Block Sequence

A welding sequence during which successive blocks are completed progressively along the joint, either from one end to the other or from the center of the joint toward either end. See also the term *block sequence*.

Progressive Die

A *die* with two or more stations arranged in line for performing two or more operations on a part; one operation is usually performed at each station.

Progressive Forming

See cultural forming at consecutive stations with a single die or separate dies.

Progressive Fracture

Cracking that extends slowly such as fatigue as opposed to fast brittle fracture.

Projected Area

The area of a cavity, or portion of a cavity, in a mold or die casting and the die measured from the projection on a plane that is normal to the direction of the mold or die opening.

Projection Lens

The final lens in the electron microscope corresponding to an ocular or projector in a compound optical microscope. This lens forms a real image on the viewing screen or photographic film.

Projection Welding

A resistance welding process that produces coalescence of metals with the heat obtained from resistance to electric current through the work parts held together under pressure by electrodes. The resulting welds are localized at predetermined points by projections, embossments, or intersections. The projections are usually crushed flat during welding. See also the term *nugget*.

Promoter

A chemical, itself a feeble catalyst, that greatly increases the activity of a given catalyst. Used in formulating plastics. See also *accelerator*.

Proof

(1) To test a component or system at its peak operating load or pressure. (2) Any reproduction of a *die impression* in any material; often a lead or plaster cast. (3) The test product of a die to confirm accuracy and quality. See also *die proof*.

Proof Load

A load, in excess of the maximum designed service load, applied to a component or structure to prove fitness for service. The amount, ratio, or percentage by which the proof load exceeds the maximum service load may be referred to as the *safety factor*.

Proof Pressure

The test pressure that pressurized components must sustain without detrimental deformation or damage. The proof pressure test is used to give evidence of satisfactory workmanship and material quality.

P

Proof Stress

(1) A specified stress to be applied to a member or structure to indicate its ability to withstand service loads. (2) The stress that will cause a specified small *permanent set* in a material. (3) The stress required to induce a specified percentage permanent strain. See *tensile test* and compare with *proof load*.

Proof Test

The test carried out on a component or assembly to confirm that it is capable of performing to the design intent. The term usually implies mechanical testing, see *proof load*, but can include electrical and other tests.

Propagation

In a metallurgical context, often the growth of a crack.

Proportional Limit

The greatest stress a material is capable of developing without a deviation from straight-line proportionality between stress and strain. See also *elastic limit* and *Hooke's law*. See also *tensile test*.

Propylene Plastics

Plastics based on polymers of propylene or copolymers of propylene with other monomers, the propylene being the greatest amount by mass. See also *polypropylenes (PP)*.

Prosthesis

A manufactured component for insertion into the human body to replace or support a defective item.

Protective Atmosphere

(1) A gas envelope surrounding the part to be brazed, welded, or thermal sprayed, with the gas composition controlled with respect to chemical composition, dewpoint, pressure, flow rate, and so forth. Examples are inert gases, combusted fuel gases, hydrogen, and vacuum. (2) The atmosphere and a heat treating or sintering furnace designed to protect the parts or compacts from oxidation, nitridation, or other contamination from the environment.

Protective Potential

The threshold value of the *corrosion potential* that has to be reached to enter a *protective potential range*.

Protective Potential Range

A range of *corrosion potential* values in which an acceptable corrosion resistance is achieved for a particular purpose.

Protein

A nitrogen organic compound of high molecular weight, from three thousand to many millions. Proteins are made up of complex

combinations of simple amino acids, and they occur in all animal and vegetable matter, but are also made synthetically. They form a necessary constituent of foods and feeds, but are also used for many commercial products, but some proteins are highly poisonous. The poison of the cobra and that of the jellyfish are proteins.

Different types of plant and animal life have different types of proteins. At least 10 different proteins are known to be essential to human body growth and maintenance, but many others may have subsidiary functions since the amino acids are selective chelating agents, separating copper, iron, and other elements from the common sodium, calcium, and potassium compounds entering the system. The simple proteins are made up entirely of the acids, but the complex or conjugated proteins also contain carbohydrates and special groups, while the cystine of hair and wool also contain sulfur. The constituent amino acids of the protein molecule are linked together with a peptide bond, and the linkage forms the backbone of the molecule, but the arrangement is not similar to the high polymers usually associated with plastics with one type of polymer, or group, repeating itself. The linkage is formed by the loss of carbon dioxide rather than by the loss of water, as in plastics.

The simplest proteins are the **protamines** with molecular weights down to about 3000. They are strongly basic, are water-soluble, and contain no sulfur. **Clupeine** in herring and **salmine** in salmon and trout are examples. The **histones** that occur in white blood corpuscles contain sulfur and are more complex. The albumens of eggs and milk are soluble in water and coagulate with heat. They also occur in plants, as in the **leucosin** of wheat. **Prolamines** are **vegetable proteins**, as the zein of corn and the gliadin of wheat. They are not an adequate human protein food without **animal proteins**.

Proteins plastics are produced by the isolation of precipitation of proteins from animal or vegetable products and hardening or condensing into stable compounds that can be molded into sheet or fiber. The oldest of the protein plastics is **casein plastic**, which was used to replace bone for toothbrush handles and buttons. It is still an important molding plastic, as it is tough and can be made in pastel shades, but it is more costly than many other molding plastics. The proteins from soybean meal or other vegetable products are condensed with aldehydes or with various mineral salts or acids to form plastics. These plastics are distinct from those made from the fatty acids of soybean or other oils.

Proton

See *atom*.

Prototype

A model suitable for use in the complete evaluation of form, design, performance, and material processing.

Protuberances

See *asperities*.

Prow Formation

See *wedge formation*.

PS

See *polystyrenes*.

P.S. Proof Stress

See *tensile test*.

Pseudobinary System

(1) A three-component or ternary alloy system in which an intermediate phase acts as a component. (2) A vertical section through a ternary diagram.

Pseudocarburizing

See *blank carburizing*.

Pseudonitriding

See *blank nitriding*.

Pseudoplastic Behavior

A decrease in viscosity with increasing shear stress. Compare with *dilatant*, *rheoplectic material*, and *thixotropy*.

PSU

See *polysulfones*.

P-T Diagram

A two-dimensional graph of phase relationships in a system of any order by means of the pressure and temperature variables.

P.T.F.E.-Polytetrafluoroethylene

A thermoplastic having a relatively high melting point, good mechanical properties, good resistance to chemical attack and very low coefficient of friction. Above about 300°C it can produce fluorine and if melted may produce hydrofluoric acid.

P-T-X Diagram

A three-dimensional graph of phase relationships in a binary system by means of the pressure, temperature, and concentration variables.

Puckering

Wrinkling or buckling in a drawn shell in an area originally inside the drawer ring.

Puckers

Local areas on prepreg material where the material has blistered and pulled away from the separator film or release paper. See also *prepreg*.

Puddle

See preferred term *molten weld pool*.

Pull Cracks

In a casting, cracks that are caused by residual stresses produced during cooling, and that result from the shape of the object.

Pulled Compact

A powder metallurgy compact expanded by internal gas pressure.

Pulled Surface

In laminated plastics, imperfections in the surface, ranging from a slight breaking or lifting in localized areas to pronounced separation of the surface from the body.

Pullover Mill

A non-reversing rolling mill through which the material is passed a number of times. Between passes the material is pulled over the top of the mill.

Pulp Molding

The process by which a resin-impregnated pulp material is preformed by application of a vacuum and subsequent molding or curing.

Pulsation Welding

Sometimes used as a synonym for *multiple-impulse welding*.

Pulse

A current of controlled duration through a resistance welding circuit.

Pulsed Arc Welding

Various electric arc welding techniques in which repeated pulses of high current are superimposed on a steady, lesser background current. Any arc welding process in which the power is cyclically varied to give short-duration pulses of either voltage or current that are significantly different from the average value. In M.I.G. (metal inert gas) welding, the background current provides the main heat source and the pulses control the mode of metal transfer from feed wire to weld pool. In T.I.G. (tungsten inert gas) welding, the background current maintains arc continuity and the pulses control the heat input into the weld zone.

Pulse Time

The duration of a pulse during resistance welding.

Pultrusion

A continuous process for manufacturing composites that have a constant cross-sectional shape. The process consists of pulling a fiber-reinforcing material through a resin impregnation bath and then through a shaping die, where the resin is subsequently cured.

Pulverization

The process of reducing metal powder particle sizes by mechanical means; also called comminution or mechanical disintegration.

P

Pumice

A porous, frothlike volcanic glass, which did not crystallize due to rapid cooling, and frothed with the sudden release of dissolved gases. Powder or ground pumice is used as an abrasive for fine polishing, in metal polishes, in scouring compounds and soaps, and in plaster and light weight concrete and pozzolanic cement. In very fine powder it is called **pounce**, when used for preparing parchment and tracing cloth. **Pouncing paper** is paper coated with pumice used for pouncing, or polishing felt hats. Pumice is grayish white, and the fine powder will float on the surface of water. The natural lump pumice contains 65–75% silica, 12–15 alumina, and 4–5 each of soda and potash.

Pumping Efficiency

In a bearing, the ratio of actual oil flow to the maximum theoretical flow for a bearing with a 180° oil film operating at an eccentricity ratio of unity.

Punch

(1) The male part of a die – as distinguished from the female part, which is called the die. The punch is usually the upper member of the complete die assembly and is mounted on the *slide* or in a *die set* for alignment (except in the inverted die). (2) In double-action draw dies, the punch is the inner portion of the upper die, which is mounted on the plunger (inner slide) and does the drawing. (3) The act of piercing or punching a hole. Also referred to as *punching*. (4) The movable tool that forces material into the die and powder molding and most metal-forming operations. (5) The movable die in a trimming press or a forging machine. (6) The tool that forces the stock through the die in rod and tube extrusion and forms the internal surface in can or cup extrusion.

Punching

(1) The die shearing of a closed contour in which the sheared out sheet metal part is scrap. (2) Producing a hole by die shearing, in which the shape of the hole is controlled by the shape of the punch and its mating die. Multiple punching of small holes is called *perforating*. See also *piercing*.

Punch Press

(1) In general, any mechanical press. (2) In particular, an end wheel gap-frame press with a fixed bed, used in piercing.

Punch Radius

The radius on the end of the punch that first contacts the work, sometimes called *nose radius*. See also the term *press*.

Punch-To-Die Clearance

See *die clearance*.

PUR

See *polyurethanes*.

Purge

The removal of air from a sintering furnace chamber by replacing it with a vacuum or an inert gas prior to the introduction of the sintering atmosphere.

Purnell Process

Similar to *austempering*.

Purple Plague

A failure mechanism in electronic components that involves the formation of brittle intermetallic compounds at aluminum wire/gold bonding pad intersections. Both moisture and temperature enhance the formation of such compounds. The term “purple plague” is used because one of the five compounds that can form appears purple to the eye when viewed through a microscope.

Push Angle

The angle between a welding electrode and a line normal to the face of the weld when the electrode is pointing forward along the weld joint. See the term *forehand welding*.

Push Bench

Equipment used for drawing moderately heavy-gage tubes by cupping sheet metal and forcing it through a die by pressure exerted against the inside bottom of the cup. See *tube manufacture*.

Pusher Furnace

A type of continuous furnace in which parts to be heated are periodically charged into the furnace in containers that are pushed along the hearth against a line of previously charged containers, thus advancing the containers toward the discharge end of the furnace, where they are removed. Pusher furnaces are widely used for heat treating and sintering of metals.

Pusher-Type Seal

A mechanical seal in which the secondary seal is pushed along the shaft or sleeve to compensate for face wear.

Push Fit

A tight fit without slack but which can be made by hand. It lies between interference fit and sliding fit. Similar to *snug fit*.

Push-Pull

Any system of loading where the load alternates between tension and compression and acts axially rather than in bending or torsion.

Push Welding

Spot or projection welding in which the force is applied manually to one electrode, and the work or backing plates take the place of the other electrode.

Putty

A mixture of calcium carbonate with linseed oil, with sometimes white lead added. It is used for cementing window glass in place and as a filler for patterns. Litharge is often added to putty for steel sash. Another putty for steel contains red lead, calcium carbonate, and linseed oil. The dry pigment for putty, **whiting putty**,

according to ASTM specifications, contains 95% calcium carbonate and 5% tinting, pigment. **White lead putty** contains 10% or more white lead mixed with the calcium carbonate. Putty powder is a mixture of lead and tin oxides, or a mixture of tin oxide and oxalic acid, or it may be merely an impure form of tin oxide. It is used in the enameling, for polishing stone and glass, and as a mild abrasive for dental polishes. **Caulking putty**, used for setting window and door frames, is made of asbestos fibers, pigments, and drying oils, or with rubber or resins. **Caulking compounds** are now composed of synthetics with usually a polysulfide rubber and a lead peroxide curing agent. They are heavy pastes of 75% to 95% solids. **Koplac 1251-5** for automobile body patching and general utility putties is a low-viscosity polyester resin with 32% styrene. In putty formulations it is used with 50% talc and a catalyst. It hardens rapidly at room temperature.

PVAC. See *polyvinyl acetate*.

PVAL. See *polyvinyl alcohol*.

PVB. See *polyvinyl butyral*.

PVC. See *polyvinyl chloride*.

PVDC. See *polyvinylidene chloride*.

PVDF. See *polyvinylidene fluoride*.

PVF. See *polyvinyl formal*.

PV Factor

The product of bearing pressure and surface velocity traditionally expressed in terms of $(\text{lb} \sqrt{\text{in}^2}) \times \text{ft/min}$; (the ISO equivalent is $\text{Pa} \cdot \text{m/s}$).

Pyramidal Plane

In noncubic crystals, any plane that intersects all three axes.

Pyrites

Iron pyrites, iron sulfide, FeS , "Fools Gold."

Pyrolysis

With respect to fibers, the thermal process by which organic precursor fiber materials, such as rayon, polyacrylonitrile (PAN), and pitch, are chemically changed into carbon fiber by the action of heat in an inert atmosphere. Pyrolysis temperatures can range from 800 to 2800°C (1470–5070°F), depending on the precursor. Higher processing graphitization temperatures of 1900–3000°C (3450–5430°F) generally lead to higher-modulus carbon fibers, usually referred to as graphite fibers. During the pyrolytic process, molecules containing oxygen, hydrogen, and nitrogen are driven from the precursor fiber, leaving continuous chains of carbon. See also *carbon fiber* and *carbon-carbon composites*.

Pyrolytic Graphite

Pyrolytic graphite is a high-purity form of carbon produced by thermal decomposition of carbonaceous gases.

The commercial manufacture of pyrolytic graphite products is a relatively new division of the graphite industry. Although this material has been known for some 50 years (glance coal, deposited carbon in gas retorts, etc.), it is only within the last 30 years that the necessary production techniques have been developed.

The manufacturing process essentially consists of bringing relatively cold, carbonaceous gases into contact with a heated surface (mandrel) and thus extracting the carbon, in the form of graphite, directly from the gas. This process is not to be confused with the

pyrolysis of resins and pitches, which is involved in the manufacture of the more common bulk or polycrystalline graphites.

Pyrolytic Materials

Essentially, pyrolytic deposition (literally, deposition by thermal decomposition) is a form of the so-called gas or vapor plating. Gas or vapor plating can be accomplished by (1) hydrogen reduction, (2) displacement, or (3) thermal decomposition. Pyrolytic deposition is accomplished by the last mechanism.

The process involves passing the vapors of a compound over a surface maintained at a temperature above the decomposition temperature of the compound in a vacuum furnace. The surface provides a source for nucleation of the desired material, which is built up to the desired section thickness.

Elemental materials are deposited from single-compound vapors, for example, carbon, from a hydrocarbon; metal, from its halide; compound materials, from mixtures of compounds, for example, boron nitride from boron halide and ammonia.

In producing coatings, the substrate serves as the surface on which the coating is deposited. Introducing self-supporting parts, the substrate serves as a mandrel or mold from which the pyrolytic material is removed after deposition.

The pyrolytic deposition process is used to produce pyrolytic graphite, as well as coatings or self-supporting structures of an extremely broad range of materials. Theoretically, the only limitation on the type of material that can be produced is that (1) it must be available in the form of a compound whose vaporization temperature is below its decomposition temperature, and (2) the desired material must separate cleanly from the vapor of the compound.

General Properties

The major benefits of pyrolytic materials are as follows:

1. Highly directional properties are obtained in some materials by the substantial degree of orientation of crystals or grains, (*Note:* Highly directional properties are only obtained in materials such as pyrolytic graphite and boron nitride, which possess the unique anisotropic graphite crystal structure).
2. High densities, equivalent to theoretical densities, are obtainable.
3. High purity of material and close control of ingredients in "alloys" are obtainable by control of the reactant gases.

All initial work has been aimed at producing high-temperature materials, primarily for aerospace use. The unique properties of these materials make them attractive for a number of commercial applications.

Materials and Forms

To date, pyrolytic graphite has been the largest-volume material produced, but newer materials include the following:

1. Graphite-boron compounds: pyrolytic graphite to which less than 2% boron has been added for increased strength and oxidation resistance as well as lower electrical resistivity.
2. Other graphite compounds: pyrolytic graphite to which varying percentages of columbium, molybdenum, or tungsten have been added.
3. Boron nitride: pyrolytic boron nitride containing 50 atm% of boron and nitrogen.

4. Carbides: pyrolytic carbides of tantalum, columbium, hafnium, and zirconium.
5. Tungsten: pyrolytic tungsten has been produced in the form of coatings and parts such as crucibles and tubes.

Coatings can be deposited on complex surfaces, providing gas impermeability in extremely thin sections. On the other hand, only those surfaces of the shape that can be exposed to the flow of gases will be coated. Also, differences in coefficients of thermal expansion between substrate and coating materials must be carefully considered.

Self-supporting shapes are limited because the material must be produced by deposition on a mandrel that must be removed after the part is formed.

Directionality Depends on Crystal Structure

The directional properties of the produced part or coating depend on the inherent crystal structure of the material. In general, materials are either highly anisotropic or nearly isotropic.

Pyrolytic deposition of material with hexagonal graphite crystal structures (i.e., pyrolytic graphite and boron nitride) results in preferred crystal orientation producing a high degree of directionality of properties. The hexagonal or layer plane alignment of the grains is essentially parallel to the substrate surface. Directionality results from strong atomic bonds within layer planes and weak bonds between layer planes, and also from the mode of heat transfer through the material, which is predominantly by lattice vibration.

Pyrolytic deposition of materials with face-centered or body-centered cubic structures (i.e., carbides and tungsten) results in relatively isotropic properties. Although such materials can have a high degree of crystal orientation, orientation does not necessarily produce directional properties.

Properties of Anisotropic Materials

Pyrolytic graphite and its compounds and boron nitride have substantial directionality of properties. The ratio of the number of crystallites with layer planes parallel to the deposition surface (i.e., α axis) to the number normal to the surface (i.e., c axis) can be varied by process control. For example, in graphite, ratios may range from 100 to 1000 to 1, compared with ratios of 3 or 4 for some commercial graphites. Orientation obtained in boron nitride has been as high as 1900 to 1.

Conductivity

One of the most useful properties of pyrolytic graphite is its insulating ability. In the direction normal to the deposition surface, pyrolytic graphite is a better insulator than the most refractory ceramic materials. In addition, the thermal conductivity parallel to the deposition surface is comparable to the more *conductive* metals, tungsten and copper. This high conductivity evens out hotspots over the total surface.

The high destruction temperature of pyrolytic graphite combined with low conductivity normal to the surface allows a surface temperature to become very high. This cuts down heat absorbed by the component by reradiating heat back to the atmosphere, thus acting as a “hyperinsulator.”

Tensile Strength Improved

Tensile strengths in the α axis are orders of magnitude higher than in the c axis. For example, at room temperature, pyrolytic graphite has

an α axis average tensile strength of about 95.2 MPa, compared with about 3.5 MPa in the c direction. The graphite-boron compound has room temperature tensile strengths of 112.2 and 4.9 MPa in the α and c axes; boron nitride has α – and c -axis tensile strengths of 84 and 4.5 MPa, respectively.

Pyrolytic graphite (like conventional graphite) offers a singular advantage of increasing in strength with increasing temperature. Preliminary data indicate that the c -axis strength decreases with temperature.

Addition of alloying elements has been found to improve c -axis strength. Additions of low concentration of less than 1% tungsten and molybdenum have increased c -axis tensile strength by 50% to 90%.

Oxidation Resistance Improved

Pyrolytic graphite has somewhat greater oxidation resistance than normal graphite due largely to its imperviousness. Addition of boron improves oxidation resistance of pyrolytic graphite by a factor of 1. Oxidation resistance of boron nitride is superior to other pyrolytic materials produced to date specifically at temperatures below 2000°C.

Other Properties

Owing to the atom-by-atom deposition process, pyrolytic materials are all near theoretical density, are impervious, and have extremely high purity levels. The materials do exhibit substantial directionality of thermal expansion, which must be carefully considered in designing components.

Properties of Isotropic Materials

Performance data on the isotropic pyrolytic materials, tungsten, and the carbides of tantalum, hafnium, and columbium are much more limited than those for the anisotropic pyrolytic materials.

As mentioned before, although such materials are considered to be isotropic (in comparison with the anisotropic materials), crystal growth does tend to provide a preferred orientation in a plane normal to the deposition surface. Thus, generally speaking, the strength of such materials is greater in the plane normal to the surface than in a plane parallel to the surface.

Carbides

The pyrolytic deposition process can be controlled to produce carbides of varying metal-to-carbon ratio, resulting in carbides of differing microhardness. The following are Knoop hardness number (K_{100}) for three carbides, hardness increasing with increasing carbon-to-metal ratio:

TaC	1400–3500
HfC	2000–3600
NbC	1700–4000

The very hard grades of carbide are extremely brittle and difficult to handle. Their strength is low but they promise to be useful as thin, well-bonded coatings.

As hardness decreases, the ductility and strength of the carbides increase. Bend strengths, except for the high-hardness grade, were found to fall in the range of 68–272 MPa; a value as high as 1030 MPa was observed for tantalum carbide low in carbon.

Tungsten

Pyrolytic tungsten, which can now be produced in thickness over 6.4 mm as coatings on components to 457 mm in diameter, has been evaluated for missile application. The increased strength and lower impurity level of pyrolytic tungsten is believed to be a major factor permitting the production of sound coatings on large rocket nozzles.

Pyrometallurgy

High-temperature *winning* or *refining* of metals.

Pyrometer

A device for measuring temperatures above the range of liquid thermometers.

Pyrometry

The measurement of temperatures, for example, by measuring the electrical resistance of wire, the thermoelectric force of a couple, the expansion of solids, liquids, or gases, the specific heat of solids, or the intensity of radiant energy per unit area.

The Measurement of High Temperature

The term usually implies temperatures above about 300°C which is about the limit of a simple mercury-in-glass thermometer although more sophisticated mercury/special glass devices can operate at higher levels. A wide variety of devices are available. The simplest technique is merely to judge the color by eye but refinements of the technique utilize standard color charts or a series of comparison filters. Such techniques are useful from about 550°C (in dull light) to about 1200°C although the results are operator sensitive. Optical pyrometers superimpose a heated filament on a background of the light from the source being measured; the calibrated filament is then heated until it just disappears, hence the description *Disappearing Filament Pyrometer*. They are useful from about 700°C to about 2000°C. Radiation pyrometer focuses the radiation on a calibrated thermocouple and has no theoretical upper limit. Electrical resistance pyrometers measure the change in resistance of a wire element, commonly platinum, that is exposed to the environment in question. They have a maximum operating temperature

of about 1000°C. Thermocouples utilize the thermoelectric effects associated with pairs of metals in contact at their high and low temperature functions and have an operating range beyond 2500°C. Pyrometric cones ("Seeger" cones) are tall combs of selected mineral compounds that commence to collapse at the tip at specific temperatures up to about 200°C. A series with a range of collapse temperatures is loaded into a furnace with the charge and their progressive collapse observed.

Pyrophoric Alloys

Metals that produce sparks when struck by steel, used chiefly for gas and cigarette lighters. The original pyrophoric alloy, or **sparking metal**, was known as **Auer metal**. A very durable alloy for cigarette lighters is **zirconium-lead** alloy containing 50% of each metal. Titanium can replace part of the zirconium, and tin can replace part of the lead, but alloys with less than 25% zirconium are not pyrophoric. The 50-50 alloy has a crystalline structure. Some metals are pyrophoric. Trimethyl aluminum, $\text{Al}(\text{CH}_3)_3$, a colorless alloy made by sodium reduction of methyl aluminum chloride, is used as pyrophoric fuel.

Pyrophoricity

The property of a substance with a large surface area to self-ignite and burn when exposed to oxygen or air.

Pyrophoric Powder

A powder whose particle self-ignite and burn upon exposure to oxygen or air. Example: fine zirconium powder.

P-X Diagram

A two-dimensional graph of the isothermal phase relationships in a binary system; the coordinates of the graph are pressure and concentration.

P-X Projection

A two-dimensional graph of the phase relationships in a binary system produced by making an orthographic projection of the phase boundaries of a *P-T-X diagram* upon a pressure-concentration plane.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Quadrivariant Equilibrium

In metals, a stable state among several conjugate phases equal to two less than the number of components, that is, having four degrees of freedom.

Qualification Test

A series of tests conducted by the procuring activity, or an agent thereof, to determine the conformance of materials, or materials system, to the requirements of a specification, normally resulting in a qualified products list under the specification. Generally, qualification under a specification requires a conformance to all tests in the specification, or it may be limited to conformance to a specific type of class, or both, under the specification. Compare with *acceptance test* and *preproduction test*.

Qualified Products List (QPL)

A list of commercial plastic products that have been pretested and found to meet the requirements of a specification, especially a government classification.

Qualitative Analysis

An analysis in which some or all of the components of a sample are identified. Compare with *quantitative analysis*.

Quality

(1) The totality of features and characteristics of a product or service that bear on its ability to satisfy a given need (fitness-for-use concept of quality). (2) Degree of excellence of a product or service (comparative concept). Often determined subjectively by comparison against an ideal standard or against similar products or services available from other sources. (3) A quantitative evaluation of the features and characteristics of a product or service (quantitative concept).

Quality Assurance

Systems and procedures in the widest sense for measuring that appropriate quality levels are identified, working practices defined, records maintained, and product quality monitored. They can be considered as the system established in advance to ensure that problems will not arise.

Quality Characteristics

Any dimension, mechanical property, physical property, functional characteristic, or appearance characteristic that can be used as a basis for measuring the quality of a unit of product or service.

Quality Control Systems

Include testing procedures and physical measurements, for ensuring that established quality standards are met. They can be considered as the system of checking that confirms that a product is of intended quality.

Quality Factor

(1) In plastics, the ratio of elastic modulus to loss modulus, measured in tension, compression, flexure, or shear. This is a nondimensional term and is the reciprocal of $\tan \delta$. (2) The reciprocal of the electrical dissipation factor, which is the ratio of the power loss in a dielectric material to the total power transmitted through it, thus the imperfection of the dielectric. Equal to the tangent of the loss angle or to the ratio of the dielectric loss to the dielectric constant.

Quality Heat Treatment

The final heat treatment intended to induce the properties required by the component in service. Previous heat treatments could have intended, for example, to produce homogenization, grain refinement, or softening between stages of cold working.

Quantitative Analysis

A measurement in which the amount of one or more components of a sample is determined. Contrast with *qualitative analysis*.

Quantitative Metallography

Determination of specific characteristics of a microstructure by quantitative measurements on micrographs or metallographic images. Quantities so measured include volume concentration of phases, grain size, particle size, mean free path between like particles or secondary phases, and surface-area-to-volume ratio of microconstituents, particles, or grains. See also *image analysis*.

Quantometer/Quantograph Analytical Instruments

They are spectrographs in which an arc is struck between an electrode and a sample of the material to be identified, sometimes in a vacuum. Either the light emitted is presented as a spectrum that is then displayed on a photographic plate to be measured on associated equipment or, alternatively, selected lines of the spectrum are measured within the instrument and the results printed. In the latter case, analysis of an item is a matter of seconds provided that it falls within the standardized range of the instrument.

Quantum

The minimum quantity or increment of physical energy.

Q

Quantum Mechanics

(1) The theoretical concepts necessary to describe and explain activities and reactions on an atomic scale in the same way as Newton's laws and other physical and mechanical laws deal with such matters on a bulk scale. (2) The modern theory of matter, of electromagnetic radiation, and of the interaction between matter and radiation; also, the mechanics of phenomena to which this theory may be applied. Quantum mechanics, also termed wave mechanics, generalizes and supersedes the older classical mechanics and Maxwell's electromagnetic theory.

Quantum Number

One of the quantities, usually discrete with integer or half-integer values, needed to characterize a quantum state of a physical system.

Quantum Theory

See *quantum mechanics*.

Quarter Hard

A *temper* of nonferrous alloys and some ferrous alloys characterized by tensile strength about midway between that of *dead soft* and *half hard* tempers.

Quartering

A method of sampling a metal powder by dividing a cone-shaped heap into four parts, selecting one of them randomly, dividing this again into four parts, and repeating the procedure until the sample is small enough for particle size analysis.

Quartz

One of the several crystalline forms of silica (SiO_2); others include cristobalite and tridymite. All occur as minerals, also synthetic. Quartz is harder than most minerals, being 7 on the Mohs scale, and the crushed material is used as an abrasive. Fused quartz or quartz glass is used for light bulbs, optical glass, crucibles, and tubes and rods in furnaces. Typical values for the maximum operating temperatures for quartz glass and competing glasses are as follows:

Glass	Temperature	
	°C	°F
Borosilicate	500	930
Aluminosilicate glass	650	1200
Doped quartz glass	800	1470
Vycor	900	1650
Quartz glass	1100	2010

The most common variety of silica. It occurs mostly in grains or in masses of a white or gray color, but often colored by impurities. Pure crystalline quartz is colorless and is called *rock crystal*. Quartz usually crystallizes in hexagonal prisms or pyramids. Many crystals are obtained from modules, called geodes, which are rounded, hollow rocks with the crystals grown on the inside surface of the cavity. These rocks range in size from very small to hundreds of pounds. The crystals are not always quartz but may be grown from

minor constituents of the rocks. A geode in limestone usually has a shell of silica, and the interior crystals are of quartz or calcite, but some geodes contain crystals of gem quality containing metal-coloring constituents. The hard, rigid *beta quartz crystals* have a latticelike molecular structure in which each silicon atom is linked to four separate oxygen atoms, each oxygen atoms being linked to two different silicon atoms. The grains in sand are often less than 0.04 in. (0.10 cm), but crystals up to 20 in. (51 cm) have been found. The specific gravity is 2.65.

Quartz crystals have the property of generating an electric force when placed under pressure and, conversely, of changing dimensions when electric field is applied. This property is termed *piezoelectric*. A *piezoelectric crystal* is made up of molecules that lack both centers and planes of symmetry. Many materials other than quartz have this property, such as Rochelle salt and ammonium dihydrogen phosphate, but most are water soluble or lack hardness. The best quartz crystals are hexagonal prisms with three large and three small cap faces. For electric use, the crystals must have no bubbles, cracks, or floors, and they should be free from twinning or change in the atomic plane. Piezoelectric quartz is used in micro-sensors that monitor emissions of spraying solvents to clean printed circuit boards.

Owing to which particular refractive powers, quartz crystal is also employed for the plates in polarization instruments and in lenses. Quartz crystals for radio-frequency control are marketed in three forms: rough-sawed blanks, cut to specified angles; semifinished blanks, machine-lapped to approximate size; and electrically finished blanks, finished by hand and electrically tested. *Synthetic quartz crystals* of large size and high purity and uniformity are grown from seed crystals suspended in an alkaline silica solution at high temperature and pressure. The synthetic crystals are purified by imposing an electric current across the crystal at 932°F (500°C), which sweeps out the sodium lamp and lithium impurities by electrolysis. The addition of lithium nitride to the sodium hydroxide solution used in the hydrothermal growing process increases the *Q* value of the crystal to the range of natural quartz crystals. The synthetic crystals are used in precision oscillators and highly selective wave filters.

Barium titanate crystals are used to replace quartz for electronic use.

Quartz is harder than most minerals, and the crushed material is much used for abrasive purposes. Finely ground quartz is also used as a filler, and powdered quartz is employed as a flux in melting metals. When quartz is fused, it loses its crystalline structure and becomes a *silica glass* with a specific gravity of 2.2. The chemical formula of this material is sometimes given as SiO_3 but is really SiO_2 repeated in a lattice structure but different from that of quartz crystal. *Fused quartz*, or *quartz glass*, withstands rapid changes of temperature without breaking. Fused quartz made from rock crystal is transparent to visible light, while fused silica is normally transparent or opaque. *Vitreosil* is fused quartz, containing 99.8% silica. It is opaque, translucent, and transparent. It transmits ultraviolet and short wavelengths, has high electrical resistance, and has a coefficient of expansion about 1/17 that of ordinary glass. *Quartz tubing* for electronic use comes in round, square, hexagonal, and other shapes. Tubing as small as 0.003 in. (0.008 cm) is flexible and as strong as steel.

Quartz fiber originally was made by extruding the molten quartz through a stream of high-pressure hot air that reduces a fluffy mass of fine fibers of random lengths. Quartz fibers are now made with many differing compositions and methods of manufacture. Fibers used for wall or mat have a diameter of 39–591 μm . (1–15 μm). *Astroquartz* and *Astroquartz II* fiber are 99.95% fused silica.

The specific gravity is 2.2, tensile strength 6,000 MPa, elastic modulus 69,000 MPa, dielectric strength 3.78, and thermal expansion over zero. It is an excellent electrical insulator. It is insoluble in water, nonhygroscopic, and resistant to halogens and most common acids but not hydrofluoric or hot phosphoric. It should not be used in strong alkali concentrations. It is used in high-temperature composites, radome and antenna applications, high-speed printed circuit boards, and insulation blankets.

Quartz yarn made from these filaments is used for weaving into tape and fabric. *Quartz paper*, or *ceramic paper*, developed by the Naval Surface Weapons Center and used to replace mica for electrical insulation, is made from quartz fiber by mixing with bentonite and sheeting on a papermaking machine. *Microquartz* is felted, fine quartz fibers for insulation.

Since quartz crystallizes more slowly than many other minerals, the natural crystals may include other minerals that were crystallized previously.

Quartzite is a rock composed of quartz grains cemented together by silica. It is firm and compact and breaks with uneven, splintery fractures. Most of the quartzites used are made up of angular grains of quartz and are white or light in color with a glistening appearance. It often resembles marble, but is harder and does not effervesce in acid. Quartzite is employed for making silica brick, abrasives, and siliceous linings for tube mills. It is also rather widely used as a structural stone and as a broken stone for roads. It is a rock and widely distributed.

Quasi-Binary System

In a ternary or higher-order system, a linear composition series between two substances, each of which exhibits congruent melting, wherein all equilibria, at all temperatures or pressures, involve only phases having compositions occurring in the linear series, so that the series may be represented as a binary on a *phase diagram*.

Quasi-Cleavage Fracture

A fracture mode that combines the characteristics of *cleavage fracture* and *dimple fracture*. An intermediate type of fracture found in certain high-strength metals.

Quasi-Hydrodynamic Lubrication

A loosely defined regime of lubrication, especially in metal working, where thin-film lubrication predominates.

Quasi-Isotropic

See *isotropic*.

Quasi-Isotropic Laminate

A laminate approximating isotropy by orientation of plies in several or more directions.

Quaternary System

The complex series of compositions produced by mixing four components in all proportions.

Quench (Plastics)

A process of shock-cooling thermoplastic materials from the molten state.

Quench

Rapidly cool in various media. Common media include, in increasing order of severity, still air, air blast, oil, water, and brine. The process is perhaps most commonly associated with a hardening of steel, but it is also encountered in other circumstances such as the preliminary steps of precipitation hardening, or it may be utilized to avoid undue oxidation at the high-temperature or to induce scale to spall off.

Quench-Age Embrittlement

Embrittlement of low-carbon steels resulting from precipitation of solute carbon at existing dislocations and from precipitation hardening of the steel caused by differences in the solid solubility of carbon in ferrite at different temperatures. Quench-age embrittlement usually is caused by rapid cooling of the steel from temperatures slightly below A_{c1} (the temperature at which austenite begins to form) and can be minimized by quenching from lower temperatures.

Quench Aging

Aging induced by rapid cooling after *solution heat treatment*. See *precipitation hardening*.

Quench Annealing

Annealing an austenitic ferrous alloy by *solution heat treatment* followed by rapid quenching.

Quench Cracking

(1) Fracture of a metal during quenching from elevated temperature. Most frequently observed in a hard-carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite. (2) Cracks occurring during or immediately following quenching as a result of stresses induced by uneven thermal contraction and/or dimensional changes associated with phase changes.

Quench Hardening

(1) Hardening suitable for alpha-beta alloys (most often certain copper to titanium alloys) by solution treating and quenching to develop a martensitic-like structure. (2) In ferrous alloys, hardening by austenitizing and then cooling at a rate such that a substantial amount of austenite transforms to martensite.

Quenching

Rapid cooling of metals (often steels) from a suitable elevated temperature. This generally is accomplished by immersion in water, oil, polymer solution, or salt, although forced air is sometimes used. See also *brine quenching*, *caustic quenching*, *direct quenching*, *fog quenching*, *forced-air quenching*, *hot quenching*, *intense quenching*, *interrupted quenching*, *oil quenching*, *press quenching*, *selective quenching*, *spray quenching*, *time quenching*, and *water quenching*.

Quenching Crack

A crack formed in a metal as a result of thermal stresses produced by rapid cooling from a high temperature.

Q

Quenching Oil

Oil used for quenching metals during a heat-treating operation. See the term *oil quenching*.

Quench Time

In resistance welding, the time from the finish of the welding operation to the beginning of tempering. Also called chill time.

Quicking

The deposition of a loosely adherent mercury film on copper alloy components by dipping in a bath of, or swabbing with, various mercury-containing solutions. Normally, no electrical current is applied. The mercury inhibits the initial nonelectrolytic, nonadherent deposition of silver when the component is introduced to the silver plating bath. The liquid mercury film can cause liquid metal attack at grain boundaries if high levels of residual stress are present, and hence,

variations in the process are sometimes used as a test to confirm freedom from such stresses.

Quicksilver

Mercury (historical).

Quill

(1) A hollow tubular shaft, designed to slide or revolve, carrying a rotating member within itself. (2) Removable spindle projection for supporting a cutting tool or grinding wheel.

Q Value

A quality factor of a magnetic core material, also called energy factor or coiled magnification factor. It represents the ratio of the reactance of a coil to its series resistance. Its specific change with the frequency is a function of the type and composition of the magnetic powder used for the core.

R

The stress ratio. See *fatigue*.

RA

See *reduction in area*.

Rabbit

A hoelike bladed tool or similar device used for stirring molten metal.

Rabbit Ear

Recess in the corner of a metal forming die to allow for wrinkling or folding of the blank.

Race (or Raceway)

The groove or path in which the rolling elements in a rolling-contact bearing operate. See the term *rolling-element bearing*.

Racking

A term used to describe the placing of metal parts to be heat treated on a rack or tray. This is done to keep parts in a proper position to avoid heat-related distortions and to keep the parts separated. See also *fixturing*.

Rad

The measure of absorbed radiation. $1 \text{ rad} = 100 \text{ ergs/g} = 0.01 \text{ J/kg}$.

Radial Crack

Damage produced in brittle materials by a hard, sharp, object pressed onto the surface. The resulting crack shape is semi-elliptical and generally perpendicular to the surface.

Radial Crushing Strength

The relative capacity of a powder metallurgy bearing specimen to resist fracture induced by a force applied between flat parallel planes in a direction perpendicular to the axis of the specimen.

Radial Distribution Function Analysis

An *x-ray diffraction* method that gives the distribution of interatomic distances present in a sample along with information concerning the frequency with which the particular distances occur.

Radial Draw Forming

The forming of sheet metals by the simultaneous application of tangential stretch and radial compression forces. The operation is done gradually by tangential contact with the die member. That type of forming is characterized by very close dimensional control.

Radial Forging

A process using two or more moving anvils or dies for producing shafts with constant or varying diameters along their length or tubes with internal or external variations. Often incorrectly referred to as *rotary forging*. See also the term *mandrel forging*.

Radial Lip Seal

A radial type of seal that features a flexible sealing member, referred to as a lip. The lip is usually of an elastomeric material. It exerts radial sealing pressure on a mating shaft in order to retain fluids and/or exclude foreign matter.

Radial Marks

Lines on a fracture surface that radiate from the fracture origin and are visible to the unaided eye or at low magnification. Radial marks result from the intersection and connection of brittle fractures propagating at different levels. Also known as shear ledges. See also *chevron pattern*.

Radial Rake

The angle between the tooth face and a radial line passing through the cutting edge in a plate perpendicular to the cutter axis.

Radial Roll

The primary driven roll of the rolling mill for rolling rings in the radial pass. The roll is supported at both ends. Also referred to as main roll. See also the terms *axial rolls* and *ring rolling*.

Radial Rolling Force

In *ring rolling*, the action produced by the horizontal pressing force of the rolling mandrel acting against the ring and the main roll.

Radial Runout

For any rotating element, the total variation from true radial position, taken in a plane perpendicular to the axis of rotation. Compare with *axial runout*.

R

Radial-Load Bearing

A bearing in which the load acts in a radial direction with respect to the axis of rotation.

Radiant Energy

Energy transmitted as *electromagnetic radiation*.

Radiant Heating**Alloy Characteristics, Other Alloys**

Traditionally, radiant heating tubes have been fabricated from Ni–Cr–Fe alloys and are welded, cast, or extruded. These materials have the benefit of possessing good heat/strength properties and are very easy to weld and handle.

The protective oxide layer in these alloys consists mainly of Cr_2O_3 . This layer is easily displaced revealing a fresh surface of metal which, in turn, oxidizes. However, this results in a thinning of the tube walls and contamination of the tube interior by loose oxides.

The oxide sealing from the tube affects the heat transfer in a negative way, which could affect the function of the recuperator and burner. It might also be exhausted into the furnace atmosphere. The useful life of the tube is also limited through the carburization of the wall or by stress cracking due to reduced strength in the remaining material.

Another common material is mullite, which is used for ceramic tubes. These are especially popular in the straight-through design as the material has a higher temperature capability than Ni–Cr–Fe. However, the ceramic tubes suffer from thermal shock sensitivity. Also, fabrication is more complicated than metallic materials since mullite cannot be welded to fit flanges and end closures.

Silicon carbide (SiC) tubes are increasing in popularity, both in straight-through applications and in single-ended recuperative (SER) systems. The advantage of this material is the possibility of increasing load. However, the limitations are fragility and difficulties of fabrication and handling.

Combinations of metallic and SiC materials in SER systems exploit the benefits of both materials and offer a range of interesting possibilities.

Alloy Characterization

A metallic Fe–Cr–Al-based alloy (APM) with a higher maximum temperature, better loading capabilities, and longer life than Ni–Cr alloys has to be utilized for the production of radiant tubes for gas-fired heating systems. The material offers better ductility and thermal shock resistance than ceramic materials.

APM is a powder metal, dispersion-strengthened ferritic alloy (Fe-21% Cr-5.7% Al), and able to withstand a maximum temperature of 1250°C in tube form. The radiant tubes are seamless and extruded.

This alloy forms a thin adherent Al_2O_3 surface oxide, which provides a good protective layer in most corrosive atmospheres, especially those that have a high carbon potential or that contain sulfur, which is common in heat-treatment processes.

A particular advantage of the Al_2O_3 layer is that it does not scale, and, therefore, there is no contamination of the burner or the product.

The high-temperature creep strength is also improved compared with conventional Fe–Cr–Al alloys. Therefore, the tubes can be used both vertically and horizontally, in straight-through as well as SER applications.

The majority of the tubes in use today are of the SER design, where the burner and exhaust system are placed on the same side of the tube. With this solution, the exhaust gases are used to preheat the gas and air, which is required for combustion resulting in major improvements in system efficiency.

Other Alloys

There is a wide array of resistance material that easily covers the whole range of industrial requirements.

Nikrothal® and other Nickel-based Alloys

Ni–Cr–Fe formulations in wire, ribbon, strip, and foil form for temperatures up to 1200°C.

Cuprothal® Alloys

Copper-based alloys, in wire and ribbon form for temperatures up to 600°C.

Kanthal SUPER®

Molybdenum disulfide elements covering a range of temperatures up to 1900°C. SUPER is ideal for the high-heating power applications and increased furnace capacities, or atmospheres that preclude many metallic elements.

Superthal® Modules

SUPER element mounted in vacuum-formed, ceramic fiber modules provides compact, high density heating power to 1550°C.

Radiant Power (Flux)

The energy emitted by a source or transported in a beam per unit time, expressed, for example, in ergs per second or watts.

Radiant Tube Furnace

A furnace in which combustion of the fuel (oil or gas) occurs in tubes, which passed through the furnace chamber. The charge is heated by radiation but not contaminated by the products of combustion.

Radiant Tubes

Tubes in which fuel is burned for supplying radiant heat to a furnace. Radiant tubes are made from heat-resistant cast or wrought iron–nickel–chromium alloys or wrought nickel–chromium alloys.

Radiation Damage

- (1) A general term for the alteration of properties of a material arising from exposure to ionizing radiation (penetrating radiation), such as x-rays, gamma rays, neutrons, heavy-particle radiation, or fission fragments in nuclear fuel material. See also *neutron embrittlement*.
- (2) Damage usually on a microscopic level but possibly affecting bulk properties, resulting from radiation of any sort. However, unless otherwise qualified the term usually implies radiation by subatomic particles in particular neutrons released by radioactive decay in nuclear reactions. Effects may include embrittlement, increase in hardness, tensile strength, and yield strength and reduction of creep strength.

Radiation Dose

A cumulative exposure to ionizing radiation during a specified period of time.

Radiation Energy

The energy of a given photon or particle in a beam of radiation, often expressed in electron volts.

Radiation Gage

An instrument for measuring the intensity and quantity of ionizing radiation.

Radiation Hardening

A form of radiation damage resulting from the formation of defects in the crystal structure, such as vacant sites or interstitial atoms, which hinders the movement of dislocations.

Radiation Intensity

In general, the quantity of radiant energy at a specified location passing perpendicularly through unit area in unit time. It may be given as number of particles or photons per square centimeter per second, or in energy units as $\text{J/m}^2 \text{ s}$.

Radiation Monitoring

The continuous or periodic measurement of the intensity of radiation received by personnel or present in any particular area.

Radiation Pyrometer

See *pyrometry*.

Radiation Quality

A term describing roughly the spectrum of radiation produced by a radiation source, with respect to its penetrating power or its suitability for a given application.

Radical

A very reactive chemical intermediate.

Radio Frequency

A frequency at which coherent *electromagnetic radiation* of energy is useful for communication purposes; roughly the range is from 10 kHz to 100 GHz.

Radio Frequency (RF) Preheating

A method of preheating plastic molding materials to facilitate the molding operation and/or reduce molding cycle time. The frequencies most commonly used are those between 10 and 100 MHz.

Radio Frequency Spectrometer

An instrument that measures the intensity of radiation emitted or absorbed by atoms or molecules as a function of frequency at frequencies from 10 kHz to 100 GHz.

Radio Frequency Spectroscopy

The branch of *spectroscopy* concerned with the measurement of the intervals between atomic and molecular energy levels that are separated by frequencies from about 10^5 to 10^9 Hz as compared to the frequencies that separate optical energy levels of about 10×10^{14} Hz.

Radio Frequency Welding

A method of welding thermoplastics using a radio frequency field to apply the necessary heat. Also known as high-frequency welding.

Radio Interference

Undesired conducted or radiated electrical disturbances, including transients, that may interfere with the operation of electrical or electronic communications equipment or other electronic equipment.

Radio Tracing

Same as *radioactive tracing*.

Radioactive

Having an isotope that spontaneously disintegrates emitting particles or radiation.

Radioactive Element

An element that has at least one isotope that undergoes spontaneous nuclear disintegration to emit positive alpha particles, negative beta particles, or gamma rays.

Radioactive Metals

Metallic elements that admit radiations that are capable of penetrating matter opaque to ordinary light. They give out light and appear luminous, also having an effect on photographic plates. The metal radium is the most radioactive of all the natural elements and was much used for luminous paints for the hands of watches and instrument pointers. Because of the emission of dangerous gamma rays, however, it has been replaced but for this purpose by radioactive isotopes of other metals. These isotopes, such as *cobalt 60*, used as a source of gamma rays, and *krypton 85*, for beta rays, are marketed selectively. Radioactive metals are used in medicine for luminous paints, for ionization, for breaking particle bonds in powdering minerals, for polymerization and other chemical reactions, and for various electronic applications.

The metals that are naturally radioactive, such as uranium and thorium, all have high atomic weights. The radiating power is atomic and is unaffected in combinations. *Radium* and other radioactive metals are changing substances. Radium gives out three types of rays; some of the other elements give out only one or two. The measure of the rate of radioactivity is the curie, which is the equivalent of the radioactivity of 0.0022 lb (1 g).

Each radioactive metal has a definite breakdown measured in half-life. *Actinium*, which is *element 89*, has a half-life of 21.7 years. It emits alpha particles to decay to *actinium K*, which is the radioactive isotope of *Francium*, and then it emits beta particles. Radioactive metals breakdown successively into other elements. By comparison of changing atomic weights, it has been deduced that the metal lead is the ultimate product, and uranium

R

the parent metal under existing stability conditions. But heavier metals, now no longer stable under present conditions, have been produced synthetically, notably plutonium. The heavy *element 103* was first produced in 1961 and named *lawrencium* in honor of the inventor of the cyclotron. Not all radiation produces radioactive materials, and by controlled radiation useful elements may be introduced into alloys in a manner not possible by metallurgy. The crystal lattice of an alloy can be expanded, or atoms displaced in the lattice, thus altering the properties of the alloy. In like manner, the molecules of plastics may be cross-linked or otherwise modified by the application of radiation. For example, ethylene bottles may be irradiated after blowing to give higher strength and stiffness. Radioactive isotopes are also used widely in chemistry and in medicine and as sources of electric power.

Radioactive Tracing

The introduction of a radioactive material to another so that the radiation can be monitored to reveal the progress of reactions or movements in the system.

Radioactivity

(1) The property of the nuclei of some isotopes to spontaneously decay (lose energy). Usual mechanisms are emission of α , β , or other particles and splitting (fissioning). Gamma rays are frequently, but not always, given off the process. (2) A particular component from a radioactive source, such as β radioactivity. See also *isotope* and *radioisotope*.

Radioanalysis

An analytical chemistry technique that uses the radiation properties of a radioactive isotope of an element for its detection and quantitative determination. It can be applied to the detection and measurement of natural and artificial radioactive isotopes. See also *isotope* and *radioisotope*.

Radiograph

A photographic shadow image resulting from uneven absorption of penetrating radiation in a test object. See also *radiography*.

Radiography

A method of nondestructive inspection in which a test object is exposed to a beam of x-rays or gamma rays and the resulting shadow image of the object is recorded on photographic film placed behind the object, or displayed on a viewing screen or television monitor (real-time radiography). Internal discontinuities are detected by observing and interpreting variations in the image caused by differences in thickness, density, or absorption within the test object. Variations of radiography include *computed tomography*, *fluoroscopy*, and *neutron radiography*. See also *real-time radiography* and *nondestructive testing*.

Radioisotope

An isotope that emits ionizing radiation during its spontaneous decay; a radioactive isotope. Also known as *radionuclide*. See also *isotope* and *radio activity*.

Radiology

The general term given to material inspection methods that are based on the differential absorption of penetrating radiation—either electromagnetic radiation of very short wavelength or particulate radiation—by the part or test piece (object) being inspected. Because of differences in density and variations in thickness of the part or differences in absorption characteristics caused by variations in composition, different portions of a testpiece absorb different amounts of penetrating radiation. These variations in the absorption of the penetrating radiation can be monitored by detecting the unabsorbed radiation that passes through the test piece. See also *radiography*.

Radionuclide

See *radioisotope*.

Radionuclide Tracer Element

A radioactive isotope or an element used to study the movement and behavior of atoms by observing the distribution and intensity of radioactivity.

Radium

The best-known radioactive metal, symbol Ra, scattered in minute quantities throughout almost all classes of rocks, but commercially obtainable only from the uranium ores monazite, carnotite, and uraninite. It is a breakdown product, and it disintegrates with a half-life of 1590 years. The metal is white, but it tarnishes rapidly in air. The melting point is about 1292°F (700°C). It was discovered in 1898 by Curie, and the original source was from the pitchblende of the Sudetenland area of Austria after extraction of thorium oxide, but most of the present supply comes from the carnotite of Zaire and from the pitchblende of western Canada. One gram of radium and 7800 lb (3538 kg) of uranium are obtained from 370 tons (336 metric tons) of pitchblende. The ratio of radium to uranium in any uranium ore is about 1:3,000,000. Radium is marketed in the form of bromides or sulfate in tubes and is extremely radioactive in these forms.

In a given interval of time, a definite proportion of the atoms break up with the expulsion of α , β , and γ rays. When an alpha particle is emitted from radium, the atoms from which it is emitted become a new substance, the inert gas *radon*, or *element 86*, with a half-life of 3.82 days. During its short life, it is a definite elemental gas, but it deposits as three isotopes in solid particles, decaying through polonium to lead. Radium is most widely known for its use in therapeutic medicine. It is also used for inspecting metal castings for flaws. *Radium-beryllium powder* is marketed for use as a neutron source.

In the metallic form, its commercial applications usually utilize its radioactive characteristics, for example, radiography and radiotherapy.

Radius

(1) A line segment joining the center of a circle and light point on the circumference or surface of the circle. (2) The length of such a line. (3) To remove the sharp edge or corner of forging stock by means of a radius or form tool.

Radius of Bend

The radius of the cylindrical surface of the pin or mandrel that comes in contact with the inside surface of the bend during bending.

In the case of free or semiguided bends to 180° in which a shim or block is used, the radius of bend is one-half the thickness of the shim or block. See also the term *bend radius*.

Radon

An inert gaseous element produced naturally by the decay of radium. It is radioactive with a half-life of about 4 days.

Rag Burr

The rough edge left on a cut surface.

Rain Erosion

A form of liquid impingement erosion in which the impinging liquid particles are raindrops. This form of the erosion is of particular concern to designers and materials selectors for external surfaces of rotary-wing and fixed-wing aircraft. See also *erosion* (*erosive wear*).

Rake

The angular relationship between the tooth face, or a tangent to the tooth face at a given point, and a given reference plane or line. See also the terms *face mill*, *radial rake*, and *single-point tool*.

Rake (of Tool)

The angle between the approach (usually the top) surface of a tool and a line perpendicular to the component surface at the cutting edge. An angle greater than 90° , termed Positive Rake, usually gives a good surface. An angle less than 90° , termed Negative Rake, allows more rapid metal removal at the expense of surface finish.

Ram

The moving or falling part of a drop hammer or press to which one of the dies is attached; sometimes applied to the upper flat die of a steam hammer. Also referred to as the *slide*. See the terms *drop hammer* and *drop hammer forging*.

Ram Travel

In forming of plastics, the distance the injection ram moves to fill the mold in injection or transfer molding.

Raman Line (Band)

A line (band) that is part of a *Raman spectrum* and corresponds to a characteristic vibrational frequency of the molecule being probed.

Raman Shift

The displacement in wave number of a *Raman line (band)* from the wave number of the incident monochromatic beam. Raman shifts are usually expressed in units of cm^{-1} . They correspond to differences between molecular vibrational, rotational, or electronic energy levels.

Raman Spectroscopy

An analysis of the intensity of Raman scattering a monochromatic light as a function of frequency of the scattered light.

Raman Spectrum

The spectrum of the modified frequencies resulting from inelastic scattering when matter is irradiated by a monochromatic beam of radiant energy. Raman spectra normally consist of lines (bands) at frequencies higher and lower than that of the incident monochromatic beam.

Ramie

A fiber use for cordage and for various kinds of coarse fabrics, and found in temperate climates as well as tropical climates. The plants grow in tall, slender stalks like hemp and belong to the nettle family. The bast fibers underneath the bark are used but are more difficult to separate than hemp fiber owing to the insolubility of the adhesive gums. The fibers are eight times stronger than cotton, four times stronger than flax, and nearly three times stronger than hemp. They are fine and white and are as silky as jute. They are not very flexible and are not, in general, suitable for weaving, but their high wet strength, absorbent qualities, and resistance to mildew make the fibers suitable for warp yarns in wool and rayon fabrics. The yarn is used also for strong, wear-resistant canvas for such products as fire hose. The fiber is valued for marine gland packings and for twine. The composition is almost pure cellulose, and the tow and waste are used for making cigarette paper. *China grass* is the hand-cleaned but not degummed fiber. It is stiff and greenish yellow. *Grass cloth* is woven fabric made in China from ramie. *Swatow grass cloth*, imported into the United States, is made of ramie fibers in parallel strands, not twisted into yarns.

Ramming

(1) Packing foundry sand, refractory, or other material into a compact mass. (2) The compacting of molding (foundry) sand in forming a mold.

Random Intermittent Welds

Intermittent welds on one or both sides of a joint in which the weld increments are deposited without regard to spacing.

Random Orientation

A condition of a polycrystalline aggregate in which the orientations of the constituent crystals are completely random relative to each other. Contrast with *preferred orientation*.

Random Pattern

(1) In *filament winding* of composites, a winding with no fixed pattern. If a large number of circuits are required for the pattern to repeat, a random pattern is approached. (2) A winding in which the filaments do not lie in an even pattern.

Random Sequence

A longitudinal welding sequence wherein the weld-bead increments are deposited at random to minimize distortion.

R

Range

In inspection, the difference between the highest and lowest values of a given *quality characteristic* within a single *sample*.

Range of Stress (S_r)

The algebraic difference between the maximum and minimum stress in one cycle—that is, the range of stress. Stress range, see *fatigue*.

$$S_r = S_{\max} - S_{\min}$$

Rankine

See *absolute temperature*.

Rapid Prototyping

The terms *agility* and an *agile manufacturing* have been applied to the operation of forward-looking companies. These terms imply a number of characteristics about the organization and operation of a company that provide for quick response to changes in customer needs, and especially the ability to minimize the time between conception and marketing of new models or new products.

One of the most important tools of an agile manufacturing organization is rapid prototyping (RP). Rapid prototyping refers to the production of a part directly from a computer file generated with a computer-aided design program. While rapid prototyping is sometimes considered to include computer numerical control machining; in most cases, it refers to building up a part from a stack of thin layers, each of which is patterned from the computer-generated three-dimensional model of the part—a process that is also called “solid free-form fabrication.”

Rapid Tooling

Rapid prototyping is evolving from just a means of making prototypes to a technique for making production tooling, chiefly dies for plastic parts.

Initially, the prototypes were quite fragile, and the various techniques produced products that could only show form. As materials improved the prototypes became stronger, the products could be tried for fit and measured. Today, some systems produce parts strong enough to run briefly in a machine and do low-volume production of parts. The good news is that there are a wide variety of rapid tooling systems; the bad news is no black-and-white answers exist on how to match a project with a system.

There are three levels of rapid tooling. Some users need only a few prototypes. Called soft tooling, these parts can usually be made from room-temperature-vulcanizing materials. The next, “bridge tooling,” includes those production situations that require up to several hundred items to cover the time between early prototype and full production. The third type, hard tooling, employees tools for actual production.

Future

Recent developments aim at reducing the amount of postprocessing required for rapidly produced molds. Researchers are also experimenting with new materials such as thermoplastics, composites, and perhaps even cement. Bolstering this work are improvements in underlying rapid prototyping hardware, particularly lasers.

Other developments in rapid tooling focus on processing new materials in existing machines. For example, one experimental rapid-production method showing good results so far marries powder injection-metal feedstocks, from injection-metal molding methods, with a rapid prototyping machine. Powder-injection metals contain a polymer that lubricates and suspends the powder as it is deposited in the rapid prototyping machine.

Other efforts in rapid tooling concern the making of production molds out of ordinary SLA resins. Although SLA epoxies would melt at typical injection-molding temperatures, judicious cooling can let molds last long enough to make a few dozen pads.

Rapid Prototyping Materials

Materials used primarily to rapidly create models of prototype parts using computer-based systems and computer-aided-design data. They are also used to make tools and limited quantities of parts.

Several systems are laser based. Stereolithography, of 3D Systems, Inc., involves sequential curing of a liquid *photopolymer* on a descending platform by an ultraviolet laser beam. Two such polymers are Ciba Geigy's **Cibatool 5170** epoxy for use with helium-cadmium lasers and **Cibatool 5180** for use with argon lasers. **Exactomer** resins, of Allied Signal, use *vinyl ethers* and cationic photoinitiators to start polymerization. DTM Corp. uses a low-power CO₂ laser beam to trace part outlines and a thin layer of powder and to sinter the powder particles. Again, layer upon layer of material was built up on a descending platform until the model is completed. Materials, called **Laserite**, include *investment-casting wax*, *nylon*, and *polycarbonate*. This system can also be used to form *iron-matrix composite* tools. In this case, thermoplastic-coated carbon-steel powder particles are tacked in place and transferred to a furnace where the coating is burned off and the powder sintered to a porous shape, and the shape infiltrated with copper. A similar laser is used by Helisys, Inc., in what is called *laminated object manufacturing*. Here, the laser cuts thin paper or film, dispensed on a roll, to the part outline, and the cut pieces are deposited on a descending table until the model is completed. The materials are heat-activated, adhesive-coated, bleached *kraft paper*, or polyester film in various colors. The paper results in a model resembling wood. The film creates water-resistant models.

In fused deposition modeling, by Stratasys, Inc., a thermoplastic or wax filament from a spool is heated, extruded, and deposited in thin layers onto a base by a robot-held dispensing head. The model is built from the base up. The materials, which include *machinable wax*, *investment-casting wax*, **Plastic P200** polyolefin, and nylonlike **Plastic P300** and **Plastic P301**, are heated just sufficiently to flow and solidify instantly upon deposition. *Acrylonitrile-butadiene-styrene* parts, having a tensile strength of 21 MPa, and *polyester* parts also have been made. A robotic extrusion system developed by IBM accepts thermoplastic pellets, including an elastomer and a machinable nylonlike material. In solid ground modeling, by Cubital Ltd. (Israel) and Cubital America, successive layers of a liquid photopolymer are exposed and cured by an ultraviolet lamp through a glass mask generated ionographically using toner and representing part cross sections. The exposed resin is then removed, and the cavity is filled with *water-soluble wax*. The layer is cooled and milled to accurate thickness, and the next layer is formed. When all the layers have been built up, the wax is dissolved, leaving the model shape. Direct shell production casting, developed at MIT and marketed by Soligen Technology, Inc., is based on three-dimensional printing. This system bypasses the modeling stage and is used directly to make metal-infiltrated, *ceramic-matrix composite* cores and molds for casting parts. A jet, similar to an ink jet but using a *colloidal silica* binder, sprays successive patterns of the part shape

onto *alumina* powder, which is compacted between powder charges. When the final layer is formed, the partially consolidated shape is removed, the binder burned off, and the shape centered and infiltrated with metal. Aluminum and stainless steel parts have been cast using molds and cores made in this way.

Rapid Solidification

The cooling or quenching of liquid (molten) metals at rates that range from $104^{\circ}\text{C s}^{-1}$ to $108^{\circ}\text{C s}^{-1}$.

Rapping

Repeated light tapping, for example, to release a pattern from a sand mold or to encourage the flow of dust deposited on the collector plates of an electrostatic precipitator.

Rare Earth Elements/Metals

The rare earths are a closely related group of highly reactive metals comprising about one-sixth of the known elements. The rare earths form a transition series including the elements of atomic number 57–71, all having three outer electrons and differing only in the inner electronic structure. Because chemical properties are determined by the outer electronic structure, it is evident why these metals are chemically alike. Although not truly members of the series, scandium and yttrium (atomic numbers 21 and 39, respectively) are frequently included with this grouping that shows the rare earth elements.

Element	Atomic No.	Element	Atomic No.
Scandium	21	Gadolinium	64
Yttrium	39	Terbium	65
Lanthanum	57	Dysprosium	66
Cerium	58	Holmium	67
Praseodymium	59	Erbium	68
Neodymium	60	Thulium	69
Promethium	61	Ytterbium	70
Samarium	62	Lutetium	71
Europium	63		

Scandium and yttrium occur together in nature with the rare earths and are similar in properties.

The rare earths are neither rare (even the scarcest are more abundant than cadmium or silver) nor earths. The term *earth* stems from the oxide mineral in which these elements were first discovered. More suitable names such as lanthanons (after lanthanum, the first member of the group) have been proposed, but the term *rare earths* persists.

Two Groups

This series of metals is frequently divided into two groups based on atomic weight and chemical properties. The “light” rare earths consist of elements with atomic number 57–63 and may be called the cerium group. The “heavy” rare earths consist of elements 64–71 as well as scandium and yttrium because of similar chemical behavior. The metals of the heavy or yttrium group are more difficult to separate from each other and, as a result, have found commercial interest only recently. Other historical terms will be filed in commercial usage and can lead to confusion. For example, *didymium* is not actually another metal in this series, but it refers to the neodymium-rich rare earth mixture left after lanthanum and cerium are removed.

Properties

The rare earth elements are metals possessing distinct individual properties that make them potentially valuable as alloying agents. They are usually reduced thermally by treating the anhydrous hydride with calcium, lithium, or other alkali metals and then remelting under vacuum to volatilize the last traces of the reductant. They can also be reduced electrolytically from fused-salt baths.

Mechanical

For the various metals of 99.5% purity, the room-temperature ultimate tensile strength ranges from 103 to 272 MPa with the elongations of 5%–25%. Strength at 427°C is about one-half that at room temperature. Therefore, the rare earths do not appear to offer any outstanding mechanical properties that would indicate their use as a base for structural alloys. Scandium has a density similar to aluminum, but the potential for high-strength-to-density materials is unknown. Yttrium provides an interesting combination of properties: density similar to titanium, a melting point of 1549°C , transparency to neutrons, and formation of one of the most stable hydrides.

Fabricability

The rare earths may be hot worked, and some of them can be fabricated cold. Small arc-cast ingots of yttrium have been reduced 95% at room temperature. The metals are poor conductors of electricity. All the metals are paramagnetic, and some are strongly ferromagnetic below room temperature.

Oxidation Resistance

Yttrium and the higher atomic number rare earths maintain a typical metallic appearance at room temperature. Lanthanum, cerium, and europium oxidize rapidly under ordinary atmospheric conditions; the other metals of the light group form a thin oxide film. Some of the rare earths, notably samarium, form a stable protective oxide in air at temperatures up to at least 593°C .

Applications

Applications of the rare earths may be divided into two general categories: the long-established uses and the newer developments that frequently require the higher-purity separated elements. Three of the older applications that still account for three-fourths of total output are rare earth-cored carbons for arc lighting; lighter flints, which are misch metal-iron alloys; and cerium oxide for polishing of glass and also salts for coloring or decolorizing of glass.

Yttrium oxide and cerium sulfide are high-melting refractories. Yttrium-stabilized zirconia ceramic materials with excellent properties are commercially available.

Misch metal is used in making aluminum alloys, and in some steels and irons. In cast iron, it opposes graphitization and produces a malleablized iron. It removes the sulfur and the oxides and completely degasifies steel. In stainless steel, it is used as a precipitation-hardening agent. An important use of misch metal is in magnesium alloys for castings. From 3% to 4% of misch metal is used with 0.2%–0.6% zirconium, both of which refine the grain and give sound castings of complex shapes. The cerium metals also added heat resistance to magnesium castings.

Ceria, cerium oxide, or ceric oxide, CeO_2 , is used in coloring ceramics and glass fiber, producing distortion-free optical glass. It is used also for decolorizing crystal glass, but, when the glass contains titania, it produces a canary-yellow color.

Neodymium is used in magnesium alloys to increase strength at elevated temperatures and is used in some glasses to reduce glare. Neodymium glass, containing small amounts of the neodymium

R

oxide, is used for color television filter plates because it transmits 90% of the blue, green, and red light rays and no more than 10% of the yellow. It thus produces truer colors and sharper contrasts in the pictures and decreases the tendency toward gray tones. Neodymium is also a dopant for yttrium–aluminum–garnet, or YAG, lasers as well as for glass lasers.

Lanthanum oxide, La_2O_3 , is a white powder used for absorbing gases in vacuum tubes. Lanthanum boride, LaB_6 , is a crystalline powder used as an electron emitter for maintaining a constant, active cathode surface. It has high electrical conductivity.

Dysprosium has a corrosion resistance that is higher than that of other cerium metals. It also has good neutron-absorption ability, with a neutron cross section of 1100 barn. The metal is paramagnetic. It is used in nuclear-reactor control rods, in magnetic alloys, and in ferrites for microwave use. It is also used in mercury vapor lamps. With argon gas in the arc area, it balances the color spectrum and gives a higher light output. Samarium has a higher neutron cross section, 5500 barn, and is used for neutron absorption in reactors.

Ytterbium metal is produced in lumps and ingots. Yttrium is more abundant in nature than lead but is difficult to extract. It is found associated with the elements 57–71, although its atomic number is 39. It is the lightest of the cerium metals except scandium. The metal is corrosion resistant to 400°C. It has a hexagonal close-packed crystal structure. Ytterbium oxide, Yb_2O_3 , and yttrium oxide, Y_2O_3 , are the usual commercial forms of these metals.

Rare earths are also used in the petroleum industry as catalysts.

Another very important use of individual rare earths is in the manufacture of solid-state microwave devices widely used in radar and communications systems. Yttrium–iron garnets are especially good, because they transmit short wave energy with low energy losses. The devices, however, are very small, so the total use of rare earths is not large.

Still another important use of individual rare earths is in the construction of lasers. A high percentage of the patent applications for new lasers involves the use of a rare earth as the active constituent of the laser.

The rare earths show interesting magnetic properties. Alloys of cobalt with the rare earths, such as cobalt–samarium, produce permanent magnets that are far superior to most of the varieties on the market, and many uses for these magnets are developing.

Many phosphors contained rare earths, and barium–phosphate–europium phosphor finds applications in x-ray films that form satisfactory images with only half the exposure time of conventional x-rays.

Yttrium–aluminum–garnets (YAG) are used in the jewelry trade as artificial diamonds. Single crystals of YAG have a very high refractive index, similar to diamond, and when these crystals are cut in the form of diamonds, they sparkle in the same manner as a diamond. Also, they are very hard so that they scratch glass, and only an expert can tell the difference between a YAG diamond and a real one.

Rare Gases

The six inert gases are helium, neon, argon, krypton, xenon, and radon. Sometimes termed the *noble gases*.

Also known as inert gases in the metallurgical industry, and as noble gases, rare gases is a general name applied to the five elements helium, neon, argon, krypton, and xenon. They are rare in that they are highly rarefied gases at ordinary temperatures and are found dissipated in minute quantities in the atmosphere and in some substances. All have zero valence and normally form no chemical combinations. The rare gases are colorless, odorless, and tasteless at ambient temperatures. However, they exhibit very

different properties when cooled to extreme low temperatures. When saturated helium, or helium-4, is cooled to 2.17 K, it becomes a superfluid. One unique property of superfluid is the ability to pass undetected through very small openings. Helium-3, the unsaturated counterpart, differs in that it is magnetic.

Types

Neon

Neon is also used in voltage-regulating tubes for radio apparatus and will respond to low voltages. In television, the neon lamp will give fluctuations from full brilliancy to total darkness as many as 100,000 times a second. Colored electric advertising signs are often referred to as neon signs, but the colors other than orange are produced by different gases.

Argon

Argon is obtained by passing atmospheric nitrogen over red-hot magnesium, forming magnesium nitride and free argon. It is also obtained by separation from industrial gases. Argon is employed in incandescent lamps to give increased light and to prevent vaporization of the filament and is used instead of helium for shielding electrodes in arc welding and as an inert blanket for nuclear fuels.

Krypton

Krypton, which occurs in the air to the extent of 1 part in 1 million, is a heavy gas used as a filler for fluorescent lamps to decrease filament evaporation and heat loss and to permit higher temperatures in the lamp. Krypton-85, obtained from atomic reactions, is a beta-ray emitter used in luminous paints for activating phosphors and also as a source of radiation.

Xenon

Xenon, another gas occurring in the air to the extent of 1 part in 11 million, is the heaviest of the rare gases. When atomic reactors are operated at high power, xenon tends to build up as a reaction product, poisoning the fuel and reducing the reactivity. Xenon lamps for military use give a clear white light known as sunlight plus north-sky light. This color does not change with the voltage, and thus the lamps require no voltage regulators. Xenon is a mild anesthetic; the accumulation from air helps to induce natural sleep, but it cannot be used in surgery since the quantity needed produces asphyxiation.

Rare Metals

These metals that are rare in the sense that they are difficult to extract and are rare and expensive commercially. They include the elements astatine, technetium, and francium. The silvery metal technetium, element 43, has been produced by bombardment of molybdenum with neutrons. Although radium is a widely distributed metal, it is classed as a rare metal. All of the ultra-heavy metallic elements, such as plutonium, which are produced synthetically, are classed as rare metals. They are called transuranic metals because they are above the heavy metal uranium in weight. They are all radioactive.

Element 99, called einsteinium, was originally named ekaholmium because it appears to have chemical properties similar to holmium. It is produced by bombarding uranium-238 with stripped nitrogen atoms. It decays rapidly to form the lighter berkelium, or element 97. Neptunium (element 93), californium (element 98), and illinium (element 61) are also made atomically. The latter also has the names florentium and promethium.

Plutonium is made from uranium-238 by absorption of neutrons from recycled fuel. The metal, 99.8% pure, is obtained by

reduction of plutonium fluoride, PuF_4 , or plutonium chloride, PuCl_3 . Plutonium-238 has a low radiation level and is used as a heat source for small water-circulating heat exchangers for naval undersea diving suits.

Plutonium-241 emits beta and gamma rays. Because all the allotropic forms are radioactive, it is a pure nuclear fuel in contrast to uranium, which is only 0.7% directly useful for fission. It is thus necessary to dilute plutonium for control. For fuel elements, it may be dispersed in stainless steel and pressed into pellets at about 871°C , or pellets may be made of plutonium carbide. Plutonium-iron alloy, with 9.5% iron, melts at 410°C . It is encased in a tantalum tube for use as a reactor fuel. Plutonium-aluminum alloy is also used.

Element 102, called nobelium, has a half-life of only 12 min. Other transuranic metals produced synthetically are americium element (95) and curium (element 96). Curium is used as a heat source in remote applications. Curium 244 is obtained as curium nitrate in the reprocessing of spent reactor fuel. It is converted to curium oxide. The by-product americium is used as a component in neutron sources. Other transuranic metals that have been produced by nuclear reactions and synthesis include fermium (element 100), mendelevium (element 101), lawrencium (element 103), rutherfordium or kurchatovium element (104), and hahnium or nielsbohrium (element 105).

Ratchet Marks

Lines or markings on a fatigue fracture surface that results from the intersection and connection of fatigue fractures propagating from multiple origins. Ratchet marks are parallel to the overall direction of crack propagation and are visible to the unaided eye or at low magnification. The term is most commonly used in the case of fatigue cracks having multiple origins such as are associated with high stresses and stress concentrations. The term is also used to describe some multi-origin ductile failures such as occur on threaded fasteners torqued until they fail.

Ratcheting

Progressive cycle inelastic deformation (growth, for example) that occurs when a component or structure is subjected to a cyclic secondary stress superimposed on a sustained primary stress. The process is called thermal ratcheting when cyclic strain is induced by cyclic changes in temperature, and isothermal ratcheting when cyclic strain is mechanical in origin (even though accompanied by cyclic changes in temperature). See *shortening* and *thermal fatigue*.

Rate of Flame Propagation

The speed at which a flame travels through a mixture of gases.

Rate of Oil Flow

The rate at which specified oil will pass through a porous sintered powder metallurgy compact under specific test conditions.

Rate of Strain Hardening

Rate of change of *true stress* with respect to *true strain* in the plastic range.

Rating Life

Currently, the fatigue life in millions of revolutions or hours at a given operating speed that 90% of a group of substantially identical rolling-element bearings will survive under a given load. The 90% rating life is frequently referred to as L_{10} -life or B_{10} -life. The rating life in revolutions can be obtained from the following equation:

$$L_{10} = \left[\frac{C}{P} \right]^k \times 10^6$$

where

C is the basic load rating (in lb)

P is the equivalent radial load (in lb)

k is a constant (3 for ball bearings and 10/3 for roller bearings)

For a rating life in hours use

$$L_{10} = \frac{16,700}{N} \left[\frac{C}{P} \right]^k$$

where N is the rotational speed in rev/min.

Rattail

A surface imperfection on a casting, occurring as one or more irregular lines, caused by expansion of sand in the mold. Compare with *buckle*.

Rayleigh Scattering

Scattering *electromagnetic radiation* by independent particles that are smaller than the wavelength of radiation. Contrast with *Compton scattering*.

Rayleigh Step Bearing

A stepped-pad bearing having one step only in each pad.

Rayon

Rayon is a general name for artificial-silk textile fibers or yarns made from cellulose nitrate, cellulose acetate, or cellulose derivatives. In general, the name *rayon* is limited to the viscose, cuprammonium, and acetate fibers, or to fibers having a cellulose base. Other synthetic-fiber groups have their own group names, such as azlon for the protein fibers and nylon for the polymeric amine fibers, in addition to individual trade names.

Viscose rayon is made by treating the cellulose with caustic soda and then with carbon disulfide to form cellulose xanthate, which is dissolved in a weak caustic solution to form the viscose.

Rayons manufactured by the different processes vary both chemically and physically. They are resistant to caustic solutions that would destroy natural silk. They are also mildewproof, durable, and easily cleaned. But they do not have the permeability and soft feel of silk. The acetate rayons are more resistant than the viscose or cuprammonium. Malacca permeability of the fibers is partly overcome by having superfine fibers so that the yarns are permeable.

R

High-tenacity rayon is produced by stretching the fibers so that the molecular chains run parallel to the filament axis, and a number of small crystalline regions act as anchors for the cellulose chains. Tire cord stretched in this way has greater tensile strength.

Razor Steel

Any steel used for razors or razor blades. Open razors and earlier “safety” blades were usually plain, high-carbon steel (typically 1.5% C), more recently “stainless” grades with about 12%–14% chromium and about 1% carbon have become the norm. All types of steel are used in the hard and likely tempered condition.

R-Curve

In fracture mechanics, a plot of crack-extension resistance as a function of stable crack extension, which is the difference between either the *physical crack size* or the *effective crack size* and the *original crack size*. *R*-curves normally depend on specimen thickness and, for some materials, on temperature and strain rate.

Reactance

That part of the impedance of an alternating current circuit that is due to capacitance or inductance.

Reaction Sintering

The sintering of a metal powder mixture consisting of at least two components that chemically react during the treatment.

Reaction Stress (Welding)

The *residual stress* that could not otherwise exist if the members or parts being welded were isolated as free bodies without connection to other parts of the structure.

Reaction-Injection Molding

Reaction-injection molding (RIM) is a process in which two or more liquid–chemical components from separate tanks are metered through-pressure supply lines to a chamber. They mix in the chamber via high-velocity impingement. The resulting mixture is then injected into a mold at low pressure, about 0.48 MPa, and at low temperature, about 66°C. This leads to a lower tooling cost and less lead time than for most other molding processes.

The process is similar in concept to an ordinary two-part epoxy mix. RIM reactants become a low-viscosity, exothermic, expanding material that readily flows into a mold. The mold-clamping machine typically is equipped with electronics that turn the mold so that material more easily flows into all cavities. When a successful series of movements is perfected, they are stored as a program to ensure uniform molding of the part.

As the mold fills, the reactants are still releasing heat while tiny bubbles swell the plastic into the finest details of the mold. Cooling coils built into the mold transfer heat to maintain an ideal working temperature. The reactants quickly harden, and parts can be removed in a few minutes.

RIM polyurethane has an integral, low-density, cellular core and a solid, high-density skin. RIM structural foam has a high strength-to-weight ratio and excellent chemical resistance. A variety of shapes can be molded this way without molded-in stresses.

The process accommodates rapid thickness variations, without sink marks. Substrates of wood, steel, or other materials can be encapsulated for fillers or for increased strength. Available RIM material systems are varied and range from flexible to rigid to structural composite. In general, RIM serves larger, thick-walled (6.4 mm or more) structural parts.

The process molds polyurethane, epoxy, and other liquid chemical systems. Mixing 2–4 components in the proper chemical ratio is accomplished by a high-pressure impingement-type mixing head, from which the mix material is delivered into the mold at low pressure, where it reacts (cures). See also *injection molding (plastics)*.

Reactive Diluent

As used in epoxy formulations, a compound containing one or more epoxy groups that functions mainly to reduce the viscosity of the mixture.

Reactive Metal

A metal that readily combines with oxygen at elevated temperatures to form very stable oxides, for example, titanium, zirconium, and beryllium. Reactive metals may also become embrittled by the interstitial absorption of oxygen, hydrogen, and nitrogen.

Reactive Sputtering (of Interference Films)

A method of revealing the microstructure of metals with the aid of physically deposited interference layers (films) that is based on an optical-contrast mechanism without chemical or morphological alteration of the specimen surface. In interference layer microscopy, light that is incident on the deposited film is reflected at the air/layer and layer/specimen interfaces. Phases with different optical constants appear in various degrees of brightness and colors. The color of a phase is determined by its optical constants and by the thickness and optical constants of the interference layer. In this process, the film material is applied by cathode sputtering, transported through a gas chamber containing a reactive gas and deposited on an anodically connected specimen. Oxygen is frequently used as reaction gas, and interaction with the sputtered material leads to deposition of oxidic interference films. See also *sputtering* and *vacuum deposition* (of interference films).

Reactor

Any vessel or container in which a reaction occurs. Where the reaction is chemical, the reactor may be no more than a simple closed vessel, possibly heated and/or pressurized, in which the reaction progresses in isolation from the external environment. In a nuclear context, the term usually implies the containment vessel, everything within it and also directly associated external equipment such as shielding.

Reagent

A substance, chemical, or solution used in the laboratory to detect, measure, or react with other substances, chemicals, or solutions. See also *reagent chemicals*.

High-purity chemicals used for analytical reactions, for testing of new reactions where the effects of impurities are unknown, and for chemical work where impurities must either be absent or at a known concentration.

Real Area of Contact

In *tribology*, the sum of the local areas of contact between two solid surfaces, formed by contacting asperities, which transmit the interfacial force between the two surfaces. Contrast with *apparent area of contact*.

Real-Time Radiography

A method of nondestructive inspection in which a two-dimensional radiographic image can be immediately displayed on a viewing screen or television monitor. This technique does not involve the creation of a latent image; instead, the unabsorbed radiation is converted into an optical or electronic signal, which can be viewed immediately or can be processed in near real time with electronic and video equipment. The principal advantage of real-time radiography over film radiography is the opportunity to manipulate the test piece during radiographic inspection. This capability allows the inspection of internal mechanisms and enhances the detection of cracks and planar defects by manipulating the part to achieve the proper orientation for floor detection. See also *radiography*.

Reamed Extrusion Ingot

A cast hollow extrusion ingot that has been machined to remove the original inside surface.

Reamer

A rotary cutting tool with one or more cutting elements called teeth, used for enlarging a hole to desired size and contour. It is supported principally by the metal around the hole it cuts.

Reaming

An operation in which a previously formed hole is sized and contoured accurately by using a rotary cutting tool (*reamer*) with one or more cutting elements (teeth). The principal support for the reamer during the cutting action is obtained from the workpiece:

1. *Form reaming*: Reaming to a contour shape.
2. *Taper reaming*: Using a special reamer for taper pins.
3. *Hand reaming*: Using a long lead reamer that permits reaming by hand.
4. *Pressure coolant reaming (or gun reaming)*: Using a multiple-lip, end cutting tools through which coolant is forced at high pressure to flush chips ahead of the tool or back through the flutes for finishing of deep holes.

Recalcence

(1) The increase in temperature that occurs after undercooling, because the rate of liberation of heat during transformation of a material exceeds the rate of dissipation of heat. (2) A phenomenon, associated with the transformation of gamma iron to alpha iron on cooling (supercooling) of iron or steel, that is revealed by the brightening (reglowing) of the metal surface owing to the sudden increase in temperature caused by the fast liberation of the latent heat of transformation. The effect is particularly pronounced in steels of eutectoid composition transforming at the eutectoid temperature. Contrast with *decalcescence*.

Recarburize

(1) To increase the carbon content of molten cast iron or steel by adding carbonaceous material, high-carbon pig iron, or a high-carbon alloy. (2) To carburize a metal part to return surface carbon lost in processing; also known as *carbon restoration*.

Recess

A groove or depression in a surface.

Reciprocal Lattice

A lattice of points, each representing a set of planes in the crystal lattice, such that a vector from the original of the reciprocal lattice to any point is normal to the crystal planes represented by that point and has a length that is the reciprocal of the plane spacing.

Reciprocal Linear Dispersion

The derivative $d\lambda/dx$, where λ is the wavelength and x is the distance along the spectrum. The reciprocal linear dispersion usually is expressed in $\text{\AA}/\text{mm}$. See also *linear dispersion*.

Reciprocating-Screw Injection Molding

A combination injection and plasticating unit in which an extrusion device with a reciprocating screw is used to plasticate the material. The injection of material into a mold can take place by direct extrusion into the mold, by reciprocating the screw as an injection plunger, or by a combination of the two. When the screw serves as an injection plunger, the unit acts as a holding, measuring, and injection chamber. See also *injection molding (plastics)*.

Reclaim Rinse

A non-flowing rinse used to recover *dragout*.

Recoil Line

See *impact line*.

Reconstruction

The process by which raw digitized detector measurements are transformed into a cross-sectional computed tomography image. See also *computed tomography*.

Recovery

(1) The time-dependent portion of the decrease in strain following unloading of a specimen at the same constant temperature as the initial test. Recovery is equal to the total decrease in strain minus the instantaneous recovery. The recovery is expressed in the same units as *instantaneous recovery*. (2) Reduction or removal of work-hardening effects in metals without motion of large-angle grain boundaries. One example is the case of some severely work-hardened steels in which heating to a modest temperature, say 250°C–350°C, affects an improvement in toughness with little loss of strength. (3) The proportion of the desired component obtained by processing an ore, usually expressed as a percentage. (4) More generally than in the above usages, the return of properties or characteristics, usually

R

desirable, that have been lost or impaired as a result of some prior treatment including radiation as well as working. The recovery may occur naturally or be induced, for example, by heat treatment. In the case of fatigue, rest periods during testing may improve fatigue life, so such rests are said to provide some recovery.

Recrystallization

(1) The formation of a new, strain-free grain structure from that existing and cold-worked metal, usually accomplished by heating. (2) The change from one crystal structure to another, as occurs on heating or cooling through a critical temperature. (3) A process, usually physical, by which one crystal species is grown at the expense of another or at the expense of others of the same substance but smaller in size. (4) The process of forming in a solid material, a new grain (crystal) structure, usually during heat treatment of a work-hardened material but also when a metal undergoes a phase change in the solid state. Recrystallization commences at individual nuclei, each of which initiates a crystal that grows outward in three dimensions until it meets its neighbor or the surface. The results of grains are equiaxed, free from strain, and the material is normally in a softened state. See also *crystallization*.

Recrystallization Annealing

Annealing cold-worked metal to produce a new grain structure without phase change.

Recrystallization Temperature

(1) The lowest temperature at which the distorted grain structure of a cold-worked metal is replaced by a new, strain-free grain structure during prolonged heating. Time, purity of the metal, and prior deformation are important factors. (2) The approximate minimum temperature at which complete recrystallization of a cold-worked metal occurs within a specified time.

Recrystallized Grain Size

(1) The grain size developed by heating cold-worked metal. The time and temperature are selected so that, although recrystallization is complete, essentially no grain growth occurs. (2) In aluminum and magnesium alloys, the grain size after recrystallization, without regard to grain growth or the recrystallized conditions. See also *recrystallization*.

Recuperator

(1) Equipment for transferring heat from gaseous products of combustion to incoming air or fuel. The incoming material passes through pipes surrounded by a chamber through which the outgoing gases pass. (2) A continuous heat exchanger in which heat is conducted from the products of combustion to incoming air through flue walls.

Recyclate Plastics

Resins made at least partially from recycled thermoplastics. In 1996, about 17% of the 225×10^6 lb (102×10^6 kg) of plastic processes by a major U.S. automaker was recyclate. Polyurethane-bonded foam made from flexible polyurethane scrap is used for carpet underlays, gymnasium mats, auto sound damping and mud guards, particleboards, and, mixed with rubber chips, and adhesive pavements on athletic fields.

Caprolactam, a nylon feedstock, is recoverable from carpets and re-usable in carpets, textiles, and molded parts. Polystyrene foam with as much as 50% recycled polystyrene is used for extruded food trays and containers. Polyethylene film scrap and stretch and shrink wrap, bottles, and trash, dry-cleaning, and merchandizing bags are reprocessed into film products and used as fillers and molded products. *Petra 140*, of Allied Signal, is a 40% glass-reinforced polyethylene terephthalate (PET) made from recycled soda bottles.

Dow Plastics has a method for incorporating as much as 10% process scrap in urethane RIM autobody panels. Miles, Inc., has a process for compression-molding parts from 100% RIM scrap regrind. Polyvinyl chloride recycled from flexible PVC wire and cable is used to mold hidden auto parts that dampen noise and resist water.

Recyclates are widely used for *plastic lumber* or *synthetic wood*. Advantages over natural wood include weight reduction, especially by foaming, and rot resistance. They also resist splintering and color fade.

Polycarbonate (PC)—ABS blends, or alloys, using 25% recyclate are used for personal-computer housings.

Glass fibers used to reinforced plastics are also recyclable. **CSX hybrid fibers**, of Phoenix Fiberglass, are reclaimed from sheet molding compound waste and suitable for mixing with virgin fibers. Deja, Inc., makes footwear from recycled tire rubber, wetsuit trimmings, old file folders, coffee filters, seat cushions, soda bottles, and other materials.

Used Rubber USA makes while it's and belts from old inner tubes and scrap rubber. Michelin Americas can incorporate as much as 10% cured rubber from discarded tires in new ones without affecting their performance. Up to 60% recycled rubber from tires is used in *Symar-T*, a thermoplastic vulcanizate from NRI Industries, which provides performance and processing quality comparable to that of conventional thermoplastic elastomers. Discarded tires are also used to produce methanol, liquid petroleum gas, and gas oil. *EEKO recyclable synthetic leather* is used for handbags.

Red Brass

A series of copper alloys including one wrought alloy (C23000) and several cast alloys (C83300–C84800). Red brass C23000 contains 84%–86% copper and the balance zinc except for small amounts (0.05% maximum) of lead and iron. The cast alloys, which include leaded red brass, have a zinc content that can range from 1.0%–2.5% (C83500) to 13%–17% (C84800), and all but C83400, which is limited to 0.20% tin, contain substantial amounts of this element; 1.0%–6.5%, depending on the alloy. Lead content of the cast alloys can be as little as 0.50% maximum (C83400) or as much as 8.0% (C84400). Some of these alloys also contain about 1% nickel and most contain smaller amounts of other metals.

C23000 is available in most wrought mill forms and is used for condenser and heat-exchanger tubing, plumbing lines, electrical conduit, fasteners, and architectural and ornamental applications. It is quite ductile in the annealed condition and can be appreciably hardened by cold work.

Standard gilding metal (C21000), used for making cheap jewelry and small-arms ammunition, contains 94%–96% copper. It has a golden-red color, is stronger and harder than copper, but has only about half the electrical conductivity.

Red Hardness/Strength

Hardness and strength of a material at red heat. The term usually implies that the material in question has these characteristics to a useful extent.

Red Heat

An imprecise term since perceptions vary with the intensity and color of the background light. In natural dim light, a dark red is readily observed at about 540°C and above about 1000°C with the color becoming much more orange/yellow.

Red Mud

A residue, containing a high percentage of iron oxide, obtained in purifying bauxite in the production of alumina in the *Bayer process*.

Red Short

Susceptible to cracking during hot working because of poor ductility. The same as hot short except that it obviously only applies to materials that are worked at red heat.

Redox Potential

This *potential* of a reversible oxidation–reduction electrode measured with respect to a *reference electrode*, corrected to the hydrogen electrode, in a given *electrode*.

Redrawing

The second and successive deep-drawing operations in which cup-like shells are deepened and reduced in cross-sectional dimensions. See also *deep drawing*.

Reduced Powder

Generic term for any metal or nonmetal powder produced by the reduction of an oxide, hydroxide, carbonate, oxalate, or other compound without melting.

Reducing

(1) A broad term applied to many hot or cold working processes for reducing the cross section of a plate, bar, or tube. (2) An abbreviation for the cold reducing process, a cold forging technique in the final stages of tube making (of tube ends). (3) A reduction in the external and internal diameters without any deliberate change in wall thickness.

Reducing Agent

(1) A compound that causes *reduction*, thereby itself becoming oxidized. (2) A chemical that, at high temperatures, lowers the state of oxidation of other batch chemicals.

Reducing Atmosphere

(1) A furnace atmosphere that tends to remove oxygen from substances or materials placed in the furnace. (2) A chemically active protective atmosphere that at elevated temperature will reduce metal oxides to their metallic state. Reducing atmosphere is a relative term and such an atmosphere may be reducing to one oxide but not to another oxide. (3) An atmosphere or welding gas flame having an excess of fuel relative to oxygen, which can have a reducing or deoxidizing effect on the workpiece.

Reducing Flame

(1) A gas flame produced with excess fuel in the inner flame. (2) A gas flame resulting from combustion of a mixture containing too much fuel or too little air. See the term *neutral flame*.

Reduction

(1) In cupping and deep drawing, a measure of the percentage decrease from blank diameter to cup diameter, or of diameter reduction in redrawing. (2) In forging, rolling, and drawing, either the ratio of the original to final cross-sectional area or the percentage decrease in cross-sectional area. (3) A reaction in which there is a decrease in valence resulting from a gain in electrons. (4) In its chemical sense, the removal, from a metal ore, of oxygen and other elements combined with the metal. (5) In manufacturing, the relationship between the original dimensions and the final dimensions, usually stated as a ratio or a percentage. Contrast with *oxidation*.

Reduction Cell

A pot or tank in which either a water solution of a salt or a fused salt is reduced electrolytically to form free metals or other substances.

Reduction in Area (RA)

(1) The difference between the original cross-sectional area of a tensile specimen and the smallest area at or after fracture as specified for the material undergoing testing. Also known as reduction of area. (2) The amount, usually expressed as a percentage, by which the cross-sectional area of a tensile test specimen is reduced at the point of failure. See *tensile test*.

Reduction of Oxide

The process of converting a metal oxide to metal by applying sufficient heat in the presence of a solid or gaseous material, such as hydrogen, having a greater attraction for the oxygen than does the metal.

Redundancy

The availability of backup systems or additional load bearing features or material to accommodate failure of one component.

Redux Bonding

A proprietary adhesive system.

Redwood Viscosity

A commercial measure of viscosity expressed as the time in seconds required for 50 cm of a fluid to flow through a tube of 10 mm length and 1.5 mm diameter at a given temperature. It is recommended that fundamental viscosity units be used.

Reeding

The operation of forming serrations and corrugations in metals by coining or embossing.

R

Reel

(1) A spool or hub for coiling or feeding wire or strip. (2) To straighten and polish a round bar by passing it between contoured rolls.

Reel Breaks

Transverse breaks or ridges on successive inner laps of a coil that results from crimping of the lead end of the coil into a gripping segmented mandrel. Also called *reel kinks*.

Re-entrant

A surface feature that points inwards. A re-entrant angle acts as a notch: a re-entrant feature on a casting prevents its removal from the mold unless the mold has special provisions or is expendable.

Reference Electrodes

A nonpolarizable *electrode* with a known and highly reproducible *potential* used for potentiometric and voltammetric analyses. See also *calomel electrode*.

Reference Material

In materials characterization, a material of definite composition that closely resembles in chemical and physical nature the material with which an analyst expects to deal; used for calibration or standardization. See also *standard reference material*.

Reference Stress

A concept whereby the creep life of a component subject to a complex stress pattern is equal to the life of a simple creep test piece tested at the reference stress.

Refined

In a purified form.

Refined Iron

Originally, good-quality wrought iron, see *Puddling process*. The term is now used more vaguely referring either to a good-quality cast iron, particularly if it has a fine grain and flake size, or to high-purity iron.

Refinement (of Grain Size)

Techniques for producing a smaller, that is, finer, grain size.

Refining

The branch of *process metallurgy* dealing with the purification of crude or impure metals. Compare with *extractive metallurgy*.

Reflectance

The ratio of the radiant power or flux reflected by a medium to the radiant power or flux incident on it; generally expressed as a percentage.

Reflection (X-Ray)

See *diffraction*.

Reflection Grating

An optical component that employs reflection off a series of fine, equidistant ridges, rather than transmission through a pattern of slots, to diffract light into its component wavelengths. The gratings used in optical instrumentation are almost exclusively reflection gratings. See also *concave grating*, *diffraction grating*, *plane grating*, and *transmission grating*.

Reflection Method

The technique of producing a diffraction pattern by x-rays or electrons that have been reflected from a specimen surface.

Reflector Sheet

A clad product consisting of a facing layer of high-purity aluminum capable of taking a high polish, for reflecting heat or light, and a base of commercially pure aluminum or an aluminum–manganese alloy, for strength and formability.

Reflow Soldering

(1) A process for joining electronic components by tinning the mating surfaces, placing them together, heating until the solder fuses, and allowing to cool in the joined position. (2) A soldering process variation in which preplaced solder is melted to produce a soldered joint or coated surface. The use of this term is not recommended by the American Welding Society.

Reflowing

(1) The brief melting of a surface, often a dip coating, to improve flatness and brightness. (2) Melting of an electrodeposit followed by solidification. The surface has the appearance and physical characteristics of a hot-dipped surface (especially tin or tin alloy plates). Also called *flow brightening*.

Reflux

In materials characterization, heating a substance at the boiling temperature and returning the condensed vapors to the vessel to be reheated.

Refractive Index

The ratio of the phase velocity of monochromatic light in a vacuum to that in a specified medium. Refractive index is generally a function of wavelength and temperature. Also known as index of refraction.

Refractories, Specialty

These are ceramic materials used in high-temperature structures or equipment. The term *high temperatures* is somewhat indefinite but usually means above about 1000°C, or temperatures at which, because of melting or oxidation, the common metals cannot be used.

In some special high-temperature applications, the so-called refractory metals such as tungsten, molybdenum, niobium, and tantalum are used.

Materials, usually ceramics, are employed where resistance to very high temperature is required, as for furnace linings and metal-melting pots. Materials with a melting point above 1580°C are called refractory, and those with melting points above 1790°C are called highly refractory. However, in addition to the ability to resist softening and deformation at the operating temperatures, other factors are considered in the choice of a refractory, especially load-bearing capacity and resistance to slag attack and spalling. Heat transfer and electrical resistivity are sometimes also important. Many of the refractories are derived directly from natural minerals, but synthetic materials are much used. To manufacture refractory products, powders of the raw materials are mixed and usually dry-pressed to form the desired shape.

The greatest use of refractories is in the steel industry, where they are used for construction of linings of equipment such as blast furnaces, stoves, and open-hearth furnaces. Other important uses of refractories are for cement kilns, glass tanks, and nonferrous metallurgical furnaces, ceramic kilns, steam boilers, and paper plants. Special types of refractories are used in rockets, jets, and nuclear power plants. Many refractory materials, such as aluminum oxide and silicon carbide, are also very hard and are used in abrasives; some applications, for example, aircraft brake linings, use both characteristics.

Refractory materials are commonly grouped into (1) those containing mainly aluminosilicates; (2) those made predominantly of silica; (3) those made of magnesite, dolomite, or chrome ore, termed basic refractories (because of their chemical behavior); and (4) a miscellaneous category usually referred to as special refractories.

Aluminosilicate Refractories

Fireclay is the raw material from which the bulk (about 70%) of refractories is manufactured. Different grades are distinguished according to the softening temperature or the pyrometric cone equivalent (PCE), the number of the standard pyrometric cone that deforms under heat treatment in the same manner as the fireclay. Thus, the minimum PCEs for low, intermediate, high, and super duty fireclays are 19, 29, 31/32, and 33, respectively. Fireclays are also classified by their working properties into two other classes: plastic (those that form a moldable mass when mixed with water) and flint (a hard, rocklike clay that does not become plastic when mixed with water). In general, flint clays have higher PCEs than plastic clays and are mixed with them to form higher-grade fireclay brick.

High-alumina refractories are made from clays that contain, in addition to the alumina (Al_2O_3) in the clay minerals, hydrates of aluminum oxide. These raise the total Al_2O_3 content and make the material more refractory. Different grades are distinguished on the basis of the total Al_2O_3 content (50%, 60%, and 70% alumina refractories).

Sillimanite and kyanite are anhydrous aluminosilicate minerals used to make special refractory objects, such as crucibles, tubes, and muffles, or as an addition to fireclay to increase refractoriness and to control its shrinkage during firing.

Silica Refractories

These account for about 15% of total production. They are made from crushed and ground quartzite (ganister) to which about 2% lime has been added to assist bonding, both before and after firing. The

quality of silica refractories is to a great extent determined by the amount of Al_2O_3 impurity; even small amounts have a deleterious effect on refractoriness. This is just opposite to the case of alumina in fireclays, where a higher alumina content means greater refractoriness. High-grade silica brick contains less than 0.6% Al_2O_3 , and even the standard grade contains less than 1%. During firing, the mineral quartz transforms to cristobalite and tridymite, the high-temperature forms of silica.

The outstanding characteristic of silica is its ability to withstand high loads at elevated temperatures, for example, as a sprung-arch roof 9–12 m wide over an open hearth. The hearth may be operated within (50°C) of the melting point of silica.

Basic Refractories

Magnesite refractories are so named because magnesium carbonate mineral was for many years the sole raw material. Since World War II, seawater has become a significant source of magnesium oxide refractory, and such material is often called seawater magnesite. In any case, the raw material was calcined to form a material largely magnesium oxide, MgO ; about 5% iron oxide is usually added before calcining.

Chrome refractories are made from chrome ore, a complex mineral containing oxides of chromium, iron, magnesium, aluminum, and other oxides crystallized in the spinel structure. These crystals are usually embedded in a less refractory matrix called gangue.

In an attempt to combine the best properties of each, magnesite and chrome are often mixed to form chrome magnesite or magnesite-chrome refractories (the first-named is the dominant constituent).

Dolomite is a mixed calcium-magnesium carbonate, which, when calcined to a mixture of MgO and CaO , is used in granular form to patch the bottoms of open hearths and also to make bricks.

Miscellaneous Materials

Special refractories are made of a great many materials, and it is possible to mention here only a few of the more important ones.

Silicon carbide, SiC , is used for many refractory shapes; its outstanding properties are good thermal and electrical conductivity (it is used to make electric heating elements for furnaces), good heat-shock resistance, strength at high temperatures, and abrasion resistance. The first silica and carbide refractories were bonded with clay so that the refractory properties of the bond placed the ultimate limit on the material. A method of making self-bonded silicon carbide has been developed to remove this limitation. Although silicon carbide tends to oxidize to form SiO_2 and either CO or CO_2 , the silica-oxidation product forms a glassy coating on the remaining material and to a certain extent protects it from further oxidation.

Insulating firebrick is made from refractory clays to which a combustible material (sawdust, cork, coal) has been added; when this burns during the firing operation, it leaves a brick of high porosity.

The low thermal conductivity of insulating brick reduces heat losses from furnaces, and the low bulk density and consequent low heat capacity reduce the amount of heat needed to bring the furnace itself up to temperature. The main disadvantage of such bricks is their low strength, but even this is useful in that they can be cut or ground to shape quite readily.

Pure oxides, of which alumina is the principal example, are used for many special refractories. Zircon and zirconia are finding increased and significant uses as refractory materials. Some, such as beryllia, thoria, and uranium oxide, are of particular interest for nuclear applications.

R

Carbides, nitrides, borides, silicides, and sulfides of various sorts have been considered refractory materials, and some study has been made of them; aside from a few carbides and nitrides, however, none has found much use.

Cermets are an intimate mixture of a metal and a nonmetal, for example, aluminum oxide and chromium.

Manufacture

Standard ceramic techniques are used. Hand molding, once widely used, is used only for special shapes and small orders. The extrusion or stiff mud process is used for plastic fireclays; very often, the extruded blanks are repressed or hydraulically rammed to form special shapes, for example, T-sections of refractory pipe. Power pressing of simple shapes is the most widely used forming method. Hot pressing and hydrostatic pressing are used for some special refractories. Slip casting is used for special refractory shapes. Fusion casting is commonly used for glass tank blocks; these are mainly either aluminum oxide or aluminum oxide with significant amounts of silica, zirconia, or both.

Refractories are generally fired in tunnel kilns, but some periodic kilns are still used, particularly for special shapes.

Some types of basic refractories, known as chemically bonded, are pressed with a chemical binder, such as magnesium oxychloride, and installed without firing. Some of these, the steel-clad refractories, are encased in a metal sheath at the time of pressing. When the refractory is heated after installation, the iron oxidizes and reacts with the refractory, forming a tight bond between the individual bricks.

In all refractory products and in unfired brick in particular, the maximum possible form density is desired. To this end, careful crushing and sizing of raw materials are carried out so that, as far as possible, the gaps between large pieces are filled with smaller particles, and the space between these with still smaller, and so on. In the case of clay refractories, it is customary to use prefired (calcined) clay or crushed, fired rejects (both are known as grog) to increase the density and to reduce the firing shrinkage.

Properties

A high melting point is, of course, necessary in a refractory, but many other properties must be considered in choosing a refractory for a specific application.

A definite melting point is characteristic of pure materials; however, actual minerals from which refractories are made, for example, clay, are far from pure and hence do not melt at a specific temperature. Rather, they form increasing amounts of liquid as the temperature is increased above a certain minimum temperature at which liquid first appears. This characteristic of gradual softening is indicated by the PCE of the material and the underload test.

High-temperature strength is important for refractories, but most materials become plastic and flow at elevated temperatures. Therefore, the rate of flow (creep rate) at a given temperature under a given load is a more important design criterion.

Thermal conductivity determines the amount of heat that will flow through a furnace wall under given conditions, and a knowledge of this property is essential to furnace design.

Thermal-shock resistance is the ability of a specimen to withstand, without cracking, a difference in temperature between one part and another. For example, if a red-hot brick is dropped into cold water, it is likely to shatter since the outside cools and contracts while the center is still hot. This cracking is often referred to

as thermal spalling, the term *spalling* meaning any cracking off of large pieces of brick. Other causes of spalling are mechanical (hitting the brick and knocking off a piece) and structural (a reaction in the brick that changes the mineral structure and causes cracking). Thermal-shock resistance is enhanced by high-strength, low Young's modulus, low thermal expansion, and sometimes, depending on conditions, high thermal conductivity. Whether or not a given specimen cracks under heat shock depends not only on the material of which it is made, but also on its size and shape and on the test conditions, for example, whether it is dropped into water or into still air at the same temperature.

Various chemical properties are important in refractories. For example, the tendency of the magnesium oxide in basic brick to hydrate, that is, to react with water to form $\text{Mg}(\text{OH})_2$, should be as low as possible. Turning to high-temperature chemistry, the rate of corrosion of refractories by molten slags and iron oxide fumes is vital to the length of service.

Carbon deposition is another chemical reaction that affects the life of refractories. The reaction is not with the refractory but is catalyzed by substances in it. When carbon monoxide, perhaps in the top of a blast furnace, comes in contact with certain iron compounds, which can occur in fireclays, its reduction to carbon is catalyzed. This carbon deposits at the site of the catalyst in the brick and causes the brick to shatter.

Refractoriness

In *refractories*, the capability of maintaining a desired degree of chemical and physical identities at high temperatures and in the environment and conditions of use.

Refractory

(1) A material (usually an inorganic, nonmetallic, ceramic material) a very high melting point with properties that make it suitable for such uses as furnace linings and kiln construction. (2) The quality of resisting heat. (3) Historically, the term implied mineral and ceramic materials used in applications such as furnace linings, but modern usage includes any material that does not react with its environment and has useful levels of strength for useful periods of time at high temperatures. See also *refractories*.

Refractory Alloy

(1) A heat-resistant alloy. (2) An alloy having at extremely high melting point. See also *refractory metals*. (3) An alloy difficult to work at elevated temperatures.

Refractory Brick

A refractory shape, the most widely used size being approximately $23 \times 11.3 \times 6.4$ (or 7.6) cm ($9 \times 4 \frac{7}{16} \times 2.5$ (or 3) in.). These rectangular units are often referred to as straight brick to differentiate them from brick shapes having related overall dimensions, such as arch, key, and wedge brick, which have some interfacial angles that depart from 90° .

Refractory Cement

A large proportion of the commercial refractory cements used for furnace and oven linings and for fillers are fireclay-silica-ganister mixtures with a refractory range of 1427°C – 1538°C .

Cheaper varieties may be mixtures of fireclay and crushed brick, fireclay and sodium silicate, or fireclay and silica sand. An important class of refractory cements is made of silicon carbide grains or silicon carbide-fire sand with clay bonds or synthetic mineral bonds. The temperature range of the ceramics is 1482°C–1871°C. Silicon carbide cements are acid resistant and have high thermal and electric conductivity. For crucible furnaces, the silicon carbide cements are widely used except for molten iron. Alumina and alumina-silicate cements are very refractory and have high thermal conductivity. Calcined kaolin, diaspore clay, mullite, sillimanite, and combinations of these make cements that are neutral to most slags and to metal attacks. They are electrical insulators. Chrome-ore cements are difficult to bond unless mixed with magnesite. A chrome-magnesite cement is made of treated magnesite and high-grade chrome ore. It sets quickly and forms a hard, dense structure. The melting point is above 1982°C. It is used particularly for hot repairs in open-hearth furnaces.

Zircon-magnesite cement is made with 25% refined zircon sand, 10% milled zircon, 15% fused magnesia, and 50% low-iron dead-burned magnesite bonded with sodium silicate. A wide range of refractory cements of varying compositions and characteristics are sold under trade names, and these are usually selected by their rated temperature resistance.

Carbofrax cement is silicon carbide with a small amount of binder in various grades for temperatures from 871°C to 1760°C, depending on the fineness and the bond. Firefrax cement is an aluminum silicate, sometimes used in mixtures with ganister for aligning furnaces. It is for temperatures up to 1649°C. Alfrax cement is fused silica also and various grades for temperatures from 899°C to 1816°C.

Refractory Hard Metals

Refractory hard metals (RHMs) are a ceramic-like class of materials made from metal-carbide particles bonded together by a metal matrix. Often classified as ceramics and sometimes called cemented or sintered carbides, these metals were developed for extreme hardness and wear resistance.

These are true chemical compounds of two or more metals in the form of crystals of very high melting point and high hardness. Because of their ceramic-like nature, they are often classified as ceramics, and they do not include the hard metallic carbides, some of which, with metal binders, have similar uses; nor do they include the hard cermets. The refractory hard metals may be single large crystals, or crystalline powder bonded to itself by recrystallization under heat and pressure. In general, parts made from them do not have binders or contain only a small percentage of stabilizing binder. The intermetallic compounds, or intermetals, are marketed regularly as powders of particle size from 150 to 325 mesh for pressing into mechanical parts or for plasma-arc deposition as refractory coatings, and the powders are referred to chemically, such as the borides, beryllides, and silicides. The oxides and carbides of the metals are also used for sintering and for coatings, and the oxides are called cermets.

The RHMs are more ductile and have better thermal shock resistance and impact resistance than ceramics, but they have lower compressive strength at high temperatures and lower operating temperatures than most ceramics. Generally, properties of RHMs are between those of conventional metals and ceramics. Parts are made by conventional powder-metallurgy compacting and sintering methods.

Many metal carbides such as SiC and BC are not RHMs but are true ceramics. The fine distinction is in particle binding: RHMs are always bonded together by a metal matrix, whereas ceramic

particles are self-bonded. Some ceramics have a second metal phase, but the metal is not used primarily for bonding.

RHM System

Tungsten Carbide

Tungsten carbide with a 3%–20% matrix of cobalt is the most common structural RHM. The low-cobalt grades are used for applications requiring wear resistance; the high-cobalt grades serve where impact resistance is required.

Tantalum Carbide/Tungsten Carbide

Tantalum carbide and tungsten carbide combined in a matrix of nickel, cobalt, and/or chromium provide an RHM formulation especially suited for a combination of corrosion and wear resistance. Some grades are almost as corrosion resistant as platinum. Nozzles, orifice plates, and valve components are typical uses.

Titanium Carbide

Titanium carbide in a molybdenum and nickel matrix is formulated for high-temperature service. Tensile compressive strengths, hardness, and oxidation resistance are high at 1093°C. Critical parts for welding and thermal metalworking tools, valves, seals, and high-temperature gauging equipment are made from grades of this RHM.

Tungsten-Titanium Carbide

Tungsten-titanium carbide (W₂TiC₂) in cobalt is used primarily for metal-forming applications such as draw dies, tube-sizing mandrels, burnishing rolls, and flaring tools. The W₂TiC₂ is a gall-resistant phase in the RHM containing tungsten carbide as well as cobalt.

Borides

Zirconium boride is a microcrystalline gray powder of the composition ZrB₂. When compressed and sintered to a specific gravity of about 5.3, it has a Rockwell A hardness of 90, a melting point of 2980°C, and a tensile strength of 241–276 MPa. It is resistant to nitric and hydrochloric acids, to molten aluminum and silicon, and to oxidation. At 1204°C, it has a transverse rupture strengths of 379 MPa. It is used for crucibles and for rocket nozzles.

Chromium boride occurs as very hard crystalline powder in several phases: the CrB orthorhombic crystal, the hexagonal crystal Cr₂B, and the tetragonal crystal Cr₃B₂. Chromium boride parts produced by powder metallurgy have a specific gravity of 6.20–7.31, with a Rockwell A hardness of 77–88. They have good resistance to oxidation at high temperatures, are stable to strong acids, and have high heat-shock resistance up to 1316°C. The transverse rupture strength is from 552 to 931 MPa. CrB is used for oil-well drilling. A sintered material, used for gas-turbine blades, contains 85% CrB with 15% nickel binder. It has a Rockwell A hardness of 87 and a transverse rupture strength of 848 MPa.

Molybdenum boride, Mo₂B, has a specific gravity of 9.3, a Knoop hardness of 1660, and a melting point of about 1660°C. Tungsten boride, W₂B, has a specific gravity of 16.7 and a melting point of 2770°C. Titanium boride, TiB₂, is light in weight with a specific gravity of 4.5. It has a melting point of about 2593°C. Molded parts made from the powder have a Knoop hardness of 3300 and a flexural strength of 241 MPa, and they are resistant to oxidation up to 982°C with a very low oxidation rate above that point to about 1371°C. They are inert to molten aluminum. Intermetal powders of beryllium-tantalum, beryllium-zirconium, and beryllium-columbium are also marketed, and they are light weight and have high strength. Sintered parts resist oxidation to 1649°C.

R

Disilicides

Molybdenum disilicide, MoSi_2 , has a crystalline structure in tetragonal prisms and has a Knoop hardness of 1240. The decomposition point is above 1870°C . It can be produced by sintering molybdenum and silicon powders or by growing single crystals from an arc melt. The specific gravity of the single crystal is 6.24. The tensile strength of sintered parts is 276 MPa, and compressive strength is 2296 MPa. The resistivity is $29\ \mu\Omega\ \text{cm}$. It is used in rod form for heating elements in furnaces. The material is brittle but can be bent to shape at temperatures above 1093°C .

Kanthal Super is an MoSi_2 rod and an inert atmosphere, the operating temperature is 1600°C . Furnace gases containing active oxygen raise the operating temperature to about 1700°C , while gases containing active hydrogen lower it to about 1350°C .

Tungsten disilicide, WSi_2 , is not as hard and not as resistant to oxidation at high temperatures, but has a higher melting point, 2050°C .

Other (Nitrides, Aluminides)

Titanium nitride, TiN , is a light brown powder with a cubic lattice crystal structure. Sintered bars are extremely hard and brittle, with a hardness above Mohs 9 and a melting point of 2950°C . It is not attacked by nitric, sulfuric, or hydrochloric acid and is resistant to oxidation at high temperatures. In recent years, titanium nitride coatings have been used to markedly extend the life of tool-steel cutters and forming tools. The coatings, golden in color, are deposited by chemical or physical vapor deposition. Aluminum nitride, AlN , when molded into shapes and sintered, forms a dense, nonporous structure with a hardness of Mohs 6. It resists the action of molten iron or silicon to 1704°C , and molten aluminum to 1427°C , but is attacked by oxygen and carbon dioxide at 760°C . At least 1% oxygen causes AlN properties to deteriorate rapidly. However, if oxygen is removed, AlN is highly thermally conductive, lightweight, and a good insulator. A newly developed process has removed oxygen concentration from AlN down to 0.5%, and subsequent nitriding and a self-purification reaction has produced commercial grade AlN .

Nickel aluminide is a chemical compound of the two metals, and when molded and sintered into shapes, has good oxidation resistance and heat resistance at high temperatures. It is a sintered nickel-aluminide material with a specific gravity of 5.9 and a transverse rupture strength of 1034 MPa at 1093°C , twice that of cobalt-bonded titanium carbide at the same temperature. The melting point is 1649°C . It resists oxidation at 1093°C . It is used for highly stressed parts in high-temperature equipment. This compound in wire form is used for welding, flame coating, and hard surfacing. An aluminum powder coated with nickel may be mixed with zirconia or alumina, which will increase the hardness and heat resistance of the nickel-aluminide coating. Columbium aluminide is used as a refractory coating as it is highly resistant for long periods at 1427°C . Tin aluminide is oxidation resistant to 1093°C , but a liquid phase forms at about this point.

Triballoy intermetallic materials are composed of various combinations of nickel, cobalt, molybdenum, chromium, and silicon. For example, one composition is 50% nickel, 32% molybdenum, 15% chromium, and 3% silicon. Another is 52% cobalt, 28% molybdenum, 17% chromium, and 3% silicon. Supplied as alloy-metal powder, welding rod, or casting stock, they can be cast, deposited as a hard-facing surface plasma-sprayed, or consolidated by powder metallurgy. The materials have exceptional wear and corrosion resistance properties in corrosive media and in air up to 1093°C . Typical applications are in pumps, valves, bearings, seals, and other parts for chemical process equipment. Also, the materials are suited for marine and saltwater applications and for parts subject to wear in atomic energy plants.

Refractory Metals

Various new techniques are being utilized to produce refractory metals and their alloys. One of these processes is powder injection molding (PIM). Over 250 PIM operations serve a diverse range of applications worldwide; cemented carbides for wear and cutting applications, tungsten or molybdenum heat sinks, niobium rocket nozzles, heavy alloy projectiles and radiation shields, and titanium golf clubs. It is interesting to note the frequent PIM successes involving components with about 100 dimensions, such as a wrist-watch case.

PIM

Currently, complex-shaped parts of tungsten-iron-nickel with 93% tungsten are also being produced by PIM. Special efforts are focused on the sintering process to develop high density and keep tight tolerances in the final components.

PAS

Plasma-activated sintering (PAS) as a means to consolidate tungsten powders is another effective process to produce dynamic compression properties.

VPS

Vacuum plasma spray (VPS) forming/sintering as a viable fabrication alternative to the near-net shape manufacturing a fully dense components of W-3.5% Ni-1% Fe, Ta-10% W, Mo-40% Re, and Nb-1% Zr alloys. Because the process allows direct shape-making in vacuum, it results in much lower oxygen and moisture pickup than conventional powder-metallurgy consolidation methods.

LPPS

Low-pressure plasma spray (LPPS) technique for depositing tungsten coatings on metallic, ceramic, and composite substrates is another novel technique.

SANS

Tungsten and molybdenum and their ongoing critical role have dominated lighting technology since the development of potassium-doped tungsten as a special dispersion-strengthened system, in which hardening centers are soft particles in the form of potassium-filled bubbles. Such bubbles act as a barrier against boundary migration and are essential for the mechanical stability of elongated grains in the doped (or non-sag) tungsten wire. A new method, based on small angle neutron scattering (SANS), has been developed to determine shaped distribution and the state of deformation of second-phase dispersoids. Correlation between the results of the SANS measurements and metal graphical examination has proved SANS to be suitable for characterizing the morphology of the bubbles and doped tungsten.

Refrigerants

Gases, or very-low-boiling-point liquids, used for the heat-absorbent cycle in refrigerating machines. The ideal refrigerant, besides having a low boiling point, should be noncorrosive,

non-flammable, and nontoxic. It must be free of water since as little as 40 ppm of water may cause freezing in the system. Ammonia is a common refrigerant. Ethyl chloride, methyl ether, carbon dioxide, and various chlorinated and fluorinated hydrocarbons marketed under trade names such as the *Freons* of the Du Pont Co. and the *Genetrons* of Allied Chemical Corp. are also used. *Dichlorodifluoromethane*, a nonflammable, colorless, odorless gas is Freon 12. *Freon E3* is a fluorated hydrocarbon which boils at 306°F (152°C) and is stable to 570°F (299°C). It is pourable at 175°F (79°C). It is used for dielectric insulating and electronic equipment. *Trichloro-monofluoromethane* is used as a refrigerant in industrial systems employing centrifugal compressors, and in indirect expansion-type air-conditioning systems. *Genetron II* is this material. *Genetron 101* has a chlorinated constituent of chlorofluorocarbons that has been implicated in the depletion of stratospheric ozone, and alternatives have been developed that are less environmentally harmful.

Of the chlorofluorocarbons, CFC-11 and CFC-12 have the highest ozone-depletion potential (ODP), with CFC-11 having an ODP of 1.0. *Hydrochlorofluorocarbons* (HCFCs) are also ozone-depleting but much less so and, thus, are viewed as temporary replacements. HCFC-22 for example, has an ODP of 0.055, and HCFC-123 has an ODP of 0.02. *Hydrofluorocarbons* being chlorine-free, have no ozone-depletion potential. A large variety of HFC mixtures are viewed as possible replacements for HCFCs and CFCs.

Regenerator

(1) Same as *recuperator* except that the gaseous products or combustion heat brick checkerwork in a chamber connected to the exhaust side of the furnace while the incoming air and fuel are being heated by the brick checkerwork in a second chamber, connected to the entrance side. At intervals, the gas flow is reversed so that incoming air and fuel contact hot checkerwork while that in the second chamber is being reheated by exhaust gases. (2) A system of heat conservation in which the heat of the process exhaust gas is extracted and returned to the cool ingoing gas. The term usually refers to pairs of honeycomb brick structures, one of which is heated by hot exhaust gas, while at the same time the other has heat extracted from it by the ingoing cold gas stream, the gas flows being alternated from time to time. However, the term may also be applied to other devices such as those with a rotating element passing through the two gas streams.

Regrind

Waste plastic material (such as spruce, runners, excess parison material, and reject parts from injection molding, blow molding, or extrusion operations) that has been reclaimed by shredding or granulating. Regrind is usually mixed with virgin compound, at a predetermined percentage, for remolding.

Regular Reflection

See *specular reflection*.

Regulator

A device for controlling the delivery of welding or cutting gas at some substantially constant pressure.

Regulus

The impure button, globule, or mass of metal formed beneath the slag in the smelting and reduction of ores. The name was first applied by alchemists to metallic antimony because it readily alloyed with gold.

Regulus Metal/Regulus of Antimony

Pure antimony.

Rehbinder Effect

Modification of the mechanical properties at or near the surface of a solid, attributable to interaction with a *surfactant*.

Reheat Cracking

Generally any cracking that develops when a component is heated following cooling from casting or other heating cycle. More specifically, the term refers to cracking in welds when they are heated either during postweld heat treatment or when they enter service. This form of damage is most common in the affected zones of low alloy creep resisting steels such as 0.5% chromium, 0.5% molybdenum, and 0.25% vanadium. Reheating of such weldments causes precipitation of alloy carbides within the grains, which are consequently strong and rigid. The grain boundaries are relatively weak and suffer creep or intergranular hot tensile failure as a result of high levels of residual stress from the welding cycle. Externally imposed stresses exacerbate the problem.

Reheat Furnace

Any furnace in which a part formed item is heated for further processing.

Reheater

In a boiler, the system of tubing in which steam is reheated following its first passage through a steam turbine.

Reinforced Concrete

This is portland cement concrete containing higher-strength, solid materials to improve its structural properties. Generally, steel wires or bars are used for such reinforcement, but for some purposes, glass fibers or chop wires have provided desired results.

Unreinforced concrete cracks under relatively small loads or temperature changes because of low tensile strength. The cracks are unsightly and can cause structural failures. To prevent cracking or to control the size of crack openings, reinforcement is incorporated in the concrete. Reinforcement can also be used to help resist compressive forces or to improve dynamic properties.

Steel usually is used in concrete. It is elastic, yet has considerable reserve strength beyond its elastic limit. Under a specific axial load, it changes in length only about 1/10 as much as concrete. In compression, steel was more than 10 times stronger than concrete, and in tension, more than 100 times stronger.

As reinforcement for concrete, steel may be used in the form of bars or rods, wire, fibers, pipe, or structural shapes such as wide-flange beams.

Bars are the most commonly used form. The size of a bar usually is specified by a number that is about eight times the nominal diameter, sizes range from No. 2, a nominal 0.6 cm bar, to No. 18, a nominal 5.7 cm bar.

R

During construction, the bars are placed in a form and then concrete from a mixture is cast to embed them. After the concrete has hardened, deformation is resisted and stresses are transferred from concrete to reinforcement by friction and adhesion along the surface of the reinforcement. The bonding may be improved mechanically by giving reinforcing bars raised surfaces, such bars are known as deformed bars. They are generally manufactured to standard specifications such as those of the American Society for Testing and Materials (ASTM). Similarly, the form wires used as reinforcement provide greater bond than smooth wires. The form wires are designed by D followed by a number equal to 100 times the nominal area in square inches.

Individual wires or bars resist stretching and tensile stress and the concrete only in the direction in which such reinforcement extends. Tensile stresses and deformations, however, may occur simultaneously in other directions. Therefore, reinforcement must usually be placed in more than one direction. For this purpose, reinforcement sometimes is assembled as a rectangular grid, with clips or welded joints at the intersections of the wires or bars. For example, prefabricated wire grids, called welded-wire fabric, often are used for slab reinforcement in highway pavement and in buildings.

Under some conditions, fiber-reinforced concrete is an alternative to such arrangements. The fiber, made of fine steel wires, glass fibers, or plastic threads, is embedded in the concrete in short lengths, often only about 2.5 cm. They are added to the concrete mixer along with the other ingredients. To achieve crack control in all directions, the fiber should be uniformly spaced, at close intervals, and randomly oriented throughout the hardened concrete. Such reinforcement also improves concrete tensile strength, ductility, and dynamic properties.

Reinforced Containing Elements

They improve some properties. The term usually refers to materials such as reinforced concrete or reinforced plastics that contain, respectively, steel bars and various fibers to improve their tensile and bending strengths.

Reinforced Molding Compound

A plastic reinforced with special fillers or fibers (glass, synthetic fibers, minerals, and so forth) to meet specific requirements.

Reinforced Plastics

Molded, formed, filament-wound, tape-wrapped, or shaped plastic parts consisting of resins to which reinforcing fibers, mats, fabrics, and so forth, have been added before the forming operation to provide some strength properties greatly superior to those of the base resin. See also *resin-matrix composites*.

Reinforced Polypropylene

Polypropylene that is reinforced with mineral fillers, such as tile, mica, and calcium carbonate, as well as glass and carbon fibers. The maximum concentration usually uses 50 wt.%, although concentrates with higher levels of filler or reinforcement are available.

Reinforced Reaction Injection Molding (RRIM)

A reaction injection molding process with a reinforcement added. See also *reaction injection molding*.

Reinforcement

A strong material bonded into a matrix to improve its mechanical properties. Reinforcements are usually long fibers, chopped fibers, whiskers, particulates, and so forth. The term is not synonymous with *filler*. The most commonly used reinforcement materials are glass (E-glass and S-glass), aramid, silicon carbide, boron, alumina, fused silica, alumina-boria-silica, and carbon/graphite. See also *carbon-carbon composites*, *ceramic-matrix composites*, *metal-matrix composites*, and *resin-matrix composites*.

Reinforcement (of Weld)

Weld metal that stands proud of the straight line joining the toes at the weld to parent metal junctions. Some authorities prefer the alternative term, "Excess," but others consider this to have an undesirably pejorative implication bearing in mind that some overfilling is normal, usually fully acceptable and preferable to insufficient filling. Where the overfill is unacceptably large, it would be termed excessive reinforcement rather than excess excess! See also *face reinforcement* and *root reinforcement*.

Rejectable

See preferred term *nonconforming*.

Relative Atomic Mass

The strictly correct term for *atomic mass*.

Relative Dielectric Constant

See *permittivity*.

Relative Humidity

(1) The ratio of the molecular fraction of water vapor present in the air to the molecular fraction of water vapor present in saturated air at the same temperature and barometric pressure. Approximately, it equals the ratio of the partial pressure or density of the water vapor in the air to the saturation pressure or density, respectively, at the same temperature. (2) The ratio, expressed as a percentage, of the amount of water vapor present in a given volume of air at a given temperature to the amount required to saturate the air at that temperature.

Relative Rigidity

In dynamic mechanical measurements of plastics, the ratio of modulus at any temperature, frequency, or time to the modulus at a reference temperature, frequency, or time.

Relative Sintering Temperature

In powder metallurgy, the ratio of the sintering temperature to the melting temperature of the substance as expressed on the Kelvin scale.

Relative Standard Deviation (RSD)

The standard deviation expressed as a percentage of the mean value:

$$\text{RSD} = 100 \left[\frac{S}{X} \right] \frac{d^2}{n-1}$$

where

S is the standard deviation

d is the difference between the individual results and the average

n is the number of individual results

X is the average of individual results

Also known as coefficient of variation.

Relative Transmittance

The ratio of the transmittance of the object in question to that of a reference object. For a spectral line on a photographic emulsion, it is the ratio of the transmittance of the photographic image of the spectral line to the transmittance of a clear portion of the photographic emulsion. Relative transmittance may be total, specular, or diffuse. See also *transmittance*.

Relative Viscosity

For a polymer in solution, the ratio of the absolute viscosities of the solution (of stated concentration) and of the pure solvent at the same temperature.

Relaxation Curve

A plot of either the remaining or relaxed stress as a function of time. See also *relaxation rate*.

Relaxation Strictly Creep Relaxation

The reduction of imposed load as a result of deformation by creep. The mechanism involves the reduction in elastic strain with a corresponding increase in plastic, that is, creep, strain. The phenomenon occurs in components such as high-temperature bolts that are subject to a fixed strain rather than a fixed stress. See *tensile test* and *displacement-controlled loading*.

Relaxation Time

(1) The time taken for some characteristic or property to reduce to a predetermined value. The term is usually used in connection with diffusion control processes such as creep. (2) The time required for a stress under a sustained constant strain to diminish by a stated fraction of its initial value.

Relaxed Stress

The initial stress minus the remaining stress at a given time during a stress-relaxation test.

Relay

An electrically controlled device that opens and closes electrical contacts to affect the operation of other devices in the same or another electric circuit.

Release Agent

In forming of plastics, a material that is applied as a thin film to the surface of a mold to keep the resin from bonding to the mold. Also called parting agent. See also *mold release agent*.

Release Film

In forming of plastics, an impermeable layer of film but does not bond to the resin being cured. See also *separator*.

Release Paper

A sheet, serving as a protectant or carrier, or both, for an adhesive film or mass, which is easily removed from the film or mass prior to use.

Reliability

A quantitative measure of the ability of a product or service to fulfill its intended function for a specified period of time.

Relief

The result of the removal of tool material behind or adjacent to the cutting edge to provide clearance and prevent rubbing (heel drag). See also *relief angle*.

Relief Angle

The angle formed between a relieved surface and a given plane tangent to a cutting edge or to a point on a cutting edge. Also known as clearance angle. See also the term *single-point tool*.

Relieving

Buffing or other abrasive treatment of the high points of an embossed metal surface to produce highlights that contrast with the finish in the recesses.

Remaining Stress

The stress remaining at a given time during a stress-relaxation test. See also *stress relaxation*.

Remanence

The magnetic induction remaining in a magnetic circuit after removal of the applied magnetizing force. Sometimes called *remanent induction*.

Renormalizing

The normalizing of steel that has undergone some process, for example, welding, that has impaired some characteristic. The term obviously implies that the steel was in the normalized condition prior to the process.

Repeatability

A term used to refer to the test result variability associated with a limited set of specifically defined sources of variability within a single laboratory.

R

Repeated Impact

See *impingement*.

Replica

A reproduction of a surface in a material. It is usually accomplished by depositing a thin film of suitable material, such as a plastic, onto the specimen surface. The film is subsequently extracted and examined by optical microscopy, scanning electron microscopy, or transmission electron microscopy, the latter being the most common. Replication techniques can be classified as either surface replication or extraction replication. Surface replicas provide an image of the surface topography of the specimen, while extraction replica lift particles from the specimen. See also *atomic replica*, *cast replica*, *collodian replica*, *Formvar replica*, *gelatin replica*, *impression replica*, *negative replica*, *oxide film replica*, *plastic replica*, *positive replica*, *preshadowed replica*, *tape replica method (faxfilm)*, and *vapor-deposited replica*.

Replicate

In electron microscopy, to reproduce using a *replica*.

Repressing

The application of pressure to a previously pressed and sintered powder metallurgy compact, usually for the purpose of improving some physical or mechanical property or four-dimensional accuracy.

Reprocessed Plastic

A thermoplastic prepared from melt-processed scrap or reject parts by a plastics processor, or from nonstandard or nonuniform virgin material. The term scrap does not necessarily connote feedstock that is less desirable or usable than virgin material. Reprocessed plastic may or may not be reformulated by the addition of fillers, plasticizers, stabilizers, or pigments.

Reproducibility

A term used to describe test result variability associated with specifically defined components of variance obtained both from within a single laboratory and between laboratories.

Rerolling Quality

Rolled *billets* from which the surface defects have not been completely removed.

Resenes

The constituents of *rosin* that cannot be saponified with alcoholic alkali, but that contain carbon, hydrogen, and oxygen in the molecule. See also *saponification*.

Reset

The realigning or adjusting of metalforming dies or tools during a production run; not to be confused with the operation *setup* that occurs before a production run.

Residual Field

Same as *residual magnetic field*.

Residual Gas Analysis (RGA)

The study of residual gases in vacuum systems using mass spectrometry.

Residual Magnetic Field

The magnetic field that remains in a part after the magnetizing forces have been removed.

Residual Method

Method of magnetic-particle inspection in which the particles are applied after the magnetizing force has been removed.

Residual Strain

The strain associated with residual stress.

Residual Stress

(1) The stress existing in a body at rest, in equilibrium, at uniform temperature, and not subjected to external forces. Often caused by the forming or thermal processing curing process. (2) An internal stress not depending on external forces resulting from such factors as cold working, phase changes, or temperature gradients. (3) Stress present in a body that is free of external forces or thermal gradients. (4) Stress remaining in a structure or member as a result of thermal or mechanical treatment or both. Stress arises in fusion welding primarily because the weld metal contracts on cooling from the solidus to room temperature. (5) Such stresses exist as an internal system with compression stresses at one location balancing tensile stresses elsewhere. They can be induced in a component by many treatments such as solidification, deformation, machining, and uneven heating or cooling (particularly welding). A simple example can be envisaged by considering a tube that is slit longitudinally producing a wide gap. The gap can be closed inducing stress round the tube circumference, and if the gap edges are welded together, the tube is left with a system of residual hoop stresses, tensile on the exterior, and compression at the bore. In some cases, the level of stress may be very high, up to yield magnitude, and often it will cause, or contribute to, many damage mechanisms including creep, fatigue, brittle fracture, and stress corrosion. Generalizing, tensile residual stresses are potentially damaging, but compressive residual stresses can be beneficial and they may be deliberately induced by painting and similar techniques. See also *stress relief*.

Residuals, Residual Elements

Elements in a metal not added deliberately. They usually remain from the original ore or remelted scrap but may be introduced from other sources such as flux or the furnace environment.

Resilience

(1) The amount of energy per unit volume released on unloading. (2) The capacity of a material, by virtue of high yield strength and low elastic modulus, to exhibit considerable elastic recovery on release of load.

Resin

A solid, semisolid, or pseudosolid organic material that has an indefinite and often high molecular weight, exhibits a tendency to flow when subjected to stress, usually has a softening or melting range, and usually fracture conchoidally. (2) Liquid resin, that is, an organic polymeric liquid, which, when converted to its final state, becomes the resin. (3) An organic polymer that cross-links to form a thermosetting plastic when mixed with a curing agent. (4) In reinforced plastics, the material used to bind together the reinforcement material; the matrix. See also *polymer*, *reinforced plastics*, and *resin–matrix composites*.

Historically, **resins** is the term applied to an important group of substances obtained as gums from trees or manufactured synthetically. It is also frequently used interchangeably with the term **plastics**. The common resin of the pinetree is called **rosin**.

Originally a category of vegetable substances soluble in ethanol but insoluble in water, resin in modern technology is generally an organic polymer of indeterminate molecular weight. The class of flammable, amorphous secretions of conifers or legumes are considered true resins, and include kauri, copal, dammar, mastic, guaiacum, jalap, colophony, shellac, and numerous less well-known substances. Water-swellable secretions of various plants, especially the Burseraceae, are called gum resins and include myrrh and olibanum. The official resins are benzoin, guaiac, mastic, and resin. Other natural resins are copal, dammar, dragon's blood, elaterium, lac, and sandarac. The natural vegetable resins are largely polyterpenes and their acid derivatives, which find application in the manufacture of lacquers, adhesives, varnishes, and inks.

The synthetic resins, originally viewed as substitutes for copal, dammar, and elemi natural resins, have a large place of their own in industry and commerce. Phenol–formaldehyde, phenolurea, and phenyl-melamine resins have an important commercially for a long time. Any unplasticized organic polymer is considered a resin; thus, nearly any of the common plastics may be viewed as a synthetic resin. Water-soluble resins are marketed chiefly as substitutes for vegetable gums and in their own right for highly specialized applications. Carboxymethylcellulose, hydroxyalkylated cellulose derivatives, modified starches, polyvinyl alcohol, polyvinylpyrrolidone, and polyacrylamides are used as thickening agents for foods, paints, and drilling muds, as fiber sizings, in various kinds of protective coatings, and as encapsulating substances.

Oleoresins are natural resins containing essential oils of the plants. Gum resins are natural mixtures of true gums and resins and are not soluble in alcohol. They include rubber, gutta percha, gamboge, myrrh, and olibanum. Some of the more common natural resins are rosin, dammar, mastic, sandarac, lac, and animi. Fossil resins, such as amber and copal, are natural resins from ancient trees, which is then chemically altered by long exposure. The synthetic resins differ chemically from natural resins, and few of the natural resins have physical properties that make them suitable for mechanical parts.

Resin Content

The amount of *resin* in a *laminate*, expressed as either a percentage of total weight or total volume.

Resin Pocket

In plastics, an apparent accumulation of excess resin in a small, localized section visible on cut edges of molded surfaces, or internal to the structure and non-visible. See also *resin-rich area*.

Resin System

A mixture of *resin* and ingredients such as catalyst, initiator, diluents, and so forth, required for the intended processing method and final product.

Resin Transfer Molding (RTM)

A process by which catalyzed resin is transferred or injected into an enclosed mold in which reinforcement has been placed. The fiberglass reinforcement is usually woven, nonwoven, or knitted fabric.

Resin–Matrix Composites

Resin–matrix composites are advanced engineering materials that contain a reinforcement (such as fibers or particles) supported by an organic (plastic) binder (matrix). Resin–matrix composites were developed in response to demands of the aerospace community for stronger, more lightweight materials. Aluminum alloys, which provide high strength and fairly high stiffness at low weight, have provided good performance and have been the primary materials used in aircraft structures over the years. However, both corrosion and fatigue in aluminum alloys have produced problems that have been costly to remedy. World War II promoted a need for materials with improved structural properties. In response, fiber-reinforced composites were developed, and by the end of the war, fiberglass-reinforced plastics had been used successfully in filament-wound rocket motors and in various other structural applications. Today, resin–matrix composites are seeing significantly expanded levels of use and components where reduced weight is critical. This is primarily a result of their tailorability as well as their high-strength- and modulus-to-density ratios. In recent years, these materials have seen applications ranging from mass-produced tennis rackets to complex aerospace structures.

Resin–matrix composite materials can be divided into two basic categories, depending on the type of reinforcement: continuous fiber-reinforced and particulate/short fiber-reinforced composites. The first of these two materials typically uses a continuous array of oriented fibers, whereas the second category uses randomly dispersed particulates or chopped fibers. Continuous fiber composites, which are the most common type of composite, are typically made up of 3–30 μm diameter fibers that are oriented and surrounded in a supportive matrix material. Generally, the fibers used in these material systems are several orders of magnitude stiffer and stronger than the surrounding matrix. Glass fiber reinforced organic–matrix composites are the most familiar and widely used and have had extensive application in industrial, consumer, military, and aerospace markets. Carbon fiber-reinforced resin–matrix composites are the most commonly applied advanced (non-fiberglass) composites. They offer extremely high specific properties, high-quality materials that are readily available, reproducible material forms, increasingly favorable cost projections, and comparative ease of manufacture. Composites reinforced with aramid, other organics, boron fibers, and silicon carbide, alumina, and other ceramic fibers are also used. The high stiffness and strength of these fibers control the characteristic engineering properties of the composite.

The continuous matrix phase functions as a supportive element to the fibers. In this capacity, fiber orientation and alignment are maintained, load is transferred between fibers, and strength is provided in nonreinforced directions. A wide variety of matrix materials are available for use with each fiber type. By far, the most extensive matrices in current use are those employing either elevated-temperature curing epoxies or room-temperature curing vinyl esters.

R

Other matrix materials include bismaleimide resins, polyamide resins, and thermoplastic resins such as polyether ether ketone (PEEK), polyphenylene sulfide (PPS), and polyetherimide (PEI).

Although there are a wide variety of processing methods for these materials, continuous fiber-reinforced composites are usually fabricated by laminating together and curing multiple fiber plies impregnated with unreacted matrix resin. Such processing facilitates the arranging of plies of material at a variety of angles. This structuring produces a stacked, laminated construction. In the aerospace industry, the angle of plies used in the laminated stack are oriented at fixed angles to the direction of the major load. The most common fixed angles are 0°, 45°, -45°, and 90° to major load axis. See *quasi-isotropic laminate*. By selecting the proper number of plies at each of these angles, composite properties and their anisotropies can be designed for strength, modulus, or even the degree of thermal expansion along each principal direction.

Resinography

The science of morphology, structure, and related descriptive characteristics as correlated with composition or conditions and with properties or behavior of resins, polymers, plastics, and their products.

Resinoid

Any of the class of thermosetting synthetic resins, either in their initial temporarily fusible state or in their final infusible state. See also *novolac* and *thermosetting*.

Resinoid Bond

An organic bond usually of the phenol formaldehyde resin type but sometimes consisting of other synthetic resins.

Resinoid Wheel

A grinding wheel bonded with a synthetic resin. See the term *grinding wheels*.

Resin-Rich Area

A significant thickness of a nonreinforced resin layer of the same composition as that within the base material. In *reinforced plastics*, a localized area filled with resin and lacking reinforcing material. See also *resin pocket*.

Resin-Starved Area

In *reinforced plastics*, a localized area of insufficient resin, usually identified by low glass, dry spots, or fiber showing on the surface.

Resintering

(1) A second sintering operation on a powder compact. (2) Sintering a repressed compact. See also *repressing*.

Resist

(1) Coating material used to mask or protect selected areas of a substrate from the action of an etchant, solder, or plating. (2)

A material applied to prevent flow of brazing filler metal into unwanted areas. (3) Coating material, lacquer, etc., applied locally on a component, or generally to equipment to prevent deposition during electroplating or to prevent dissolution during etching. Also called *stop-off*, etc.

Resistance

The opposition that a device or material offers to the flow of direct current, equal to the voltage drop across the element divided by the current through the element. Also called electrical resistance.

Resistance Alloys

Electrical resistance alloys include both the types used in instruments and control equipment to measure and regulate electrical characteristics and those used in furnaces and appliances to generate heat. In the former applications, properties near ambient temperature are of primary interest; in the latter, elevated-temperature characteristics are of prime importance. In common commercial terminology, electrical resistance alloys used for control or regulation of electrical properties are called resistance alloys, and those used for generation of heat are referred to as resistance heating alloys.

The primary requirements for resistance alloys are uniform resistivity, stable resistance (no time-dependent aging effects), reproducible temperature coefficient of resistance, and low thermal electric potential versus copper. Properties of secondary importance are coefficient of expansion, mechanical strength, ductility, corrosion resistance, and ability to be joined to other metals by soldering, brazing, or welding. Alloys must be strong enough to withstand fabrication operations, and it must be easy to procure an alloy that has consistently reproducible properties and order to ensure resistor accuracy.

Resistors for electrical and electronic devices may be divided into two arbitrary classifications: those employed in precision instruments in which overall error is considerably less than 1%, and those employed where less precision is needed. The choice of alloys for a specific resistor application depends on the variation and properties that can be tolerated. Materials for resistors include copper-nickel (2%–22% Ni) alloys, generally referred to as radio alloys; copper-manganese-nickel alloys (10%–13% Mn and 4% Ni), generally referred to as manganins; constantin alloys, whose compositions vary from 50Cu–50Ni to 65Cu–35Ni; nickel-chromium-aluminum alloys that nominally contains 20% Cr, 3% Al, and 2%–5% of copper, iron, and/or manganese; 80Ni–20Cr alloys; and iron-chromium-aluminum alloys (nominally 73Fe–22Cr–5Al).

Resistance heating elements are used in many varied applications—from small household appliances to large industrial process heating systems and furnaces that may operate continuously at temperatures of 1300°C (2350°F) or higher. The primary requirements of materials used for heating elements are high melting point, high electrical resistivity, reproducible temperature coefficient of resistance, good oxidation resistance, absence of volatile components, and resistance to contamination. Other desirable properties are good creep strength, high emissivity, low thermal expansion, and low modulus (both of which help minimize thermal fatigue), good resistance to thermal shock, and good strength and ductility at fabricating temperature.

The most commonly used resistance heating alloys are nickel-chromium and nickel-chromium-iron alloys. Other materials include iron-chromium-aluminum alloys similar in composition to resistor alloys, high-melting temperature pure metals, and

nonmetallic materials, which can be used effectively at temperatures as high as 1900°C (3450°F).

Resistance Brazing

A resistance joining process in which the workpieces are heated locally and filler metal that is preplaced between the workpieces is melted by the heat obtained from resistance to the flow of electric current through the electrodes and the work. In the usual application of resistance brazing, the heating current is passed through the joint itself.

Resistance Butt Welding

Resistance welding processes in which the components are butt joined, that is, face as edge to edge, as opposed to a lap joint. See preferred term *flash welding* and *upset welding*.

Resistance Heating

Resistance heating is the generation of heat by electric conductors carrying current. The degree of heating for a given current is proportional to the electrical resistance of the conductor. If resistance is high, a large amount of heat is generated, and the material is used as a resistor rather than as a conductor.

Resistor Materials

In addition to having high resistivity, heating elements must be able to withstand high temperatures without deteriorating or sagging. Other desirable characteristics are low-temperature coefficient of resistance, low cost, and deformability, and availability of materials. Most commercial resistance alloys containing chromium or aluminum or both, because a protective coating of chrome oxide or aluminum oxide forms on the surface upon heating and inhibits or retards further oxidation.

Heating Element Forms

Because heat is transmitted by radiation, convection, conduction, or combinations of these, the form of element is designed for the major mode of transmission. The simplest form is the helix, using a round wire resistor, with the pitch of the helix approximately three wire diameters. This form is adapted to radiation and convection and is generally used for room or air heating. It is also used in industrial furnaces, utilizing forced convection up to about 650°C. Such helices are stretched over grooved high-aluminum refractory insulators and are otherwise open and unrestricted. These helices are suitable for mounting in air ducts or enclosed chambers, where there is no danger of human contact.

For such applications as water heating, electric range units, and die heating, where complete electrical isolation is necessary, the helix is embedded in magnesium oxide inside a metal tube, after which the tube is swaged to a small diameter to compact the oxide and increase thermal conductivity. Such units can then be formed and flattened into desired shapes. The metal tubing is usually copper for water heaters and stainless steel for radiant elements, such as range units. In some cases, the tubes may be cast into finned aluminum housings, or fins may be brazed directly to the tubing to increase surface area for convection heating.

Modification of the helix for high-temperature furnaces involves supporting each turn in a grooved refractory insulator,

with the insulators strung on stainless alloy rods. Wire sizes for such elements are 5 mm in diameter or larger, or they may be edge-wound strap. Such elements may be used up to 980°C furnace temperature.

Another form of furnace heating element is the sinuous grid element, made of heavy wire or strap or casting and suspended from refractory or stainless supports built into the furnace walls, floor, and roof.

Silicon carbide elements are in rod form, with low-resistance integral terminals extending through the furnace walls.

Direct Heating

When heating metal strip or wire continuously, the supporting rolls can be used as electrodes, and the strip or wire can be used as the resistor.

Molten Salts

The electrical resistance of molten salts between immersed electrodes can be used to generate heat. Limiting temperatures are dependent on decomposition or evaporation temperatures of the salt. Parts to be heated are immersed in the salt. Heating is rapid and, since there is no exposure to wear, oxidation is largely prevented. Disadvantages are the personnel hazards and discomfort of working close to molten salts.

Major Applications

A major application of resistance heating is in electric home appliances, including electric ranges, clothes dryers, water heaters, coffee percolators, portable radiant heaters, and hair dryers. Resistance heating has also found application in home or space heating; some homes are designed with suitable thermal insulation to make electric heating practicable.

Resistance Seam Welding

A resistance welding process that produces coalescence at the faying surfaces by the heat obtained from resistance to electric current through workpieces that are held together under pressure by electrode wheels. The resulting weld is a series of overlapping resistance spot welds made progressively along a joint by rotating the electrodes. See the term *longitudinal resistance seam welding*.

Resistance Soldering

Soldering in which the joint is heated by electrical resistance. Filler metal is either face fed into the joint or preplaced in the joint.

Resistance Spot Welding

A process in which faying surfaces are joined in one or more spots by the heat generated by resistance to the flow of electric current through workpieces that are held together under force by electrodes. The contacting surfaces in the region of current concentration are heated by a short-time pulse of low-voltage, high-amperage current to form a fused nugget of weld metal. When the flow of current ceases, the electrode force is maintained while the weld metal rapidly cools and solidifies. The electrodes are retracted after each weld, which usually is completed in a fraction of a second.

R

Resistance Strain Gauge

A strip, wire, etc., of material where the electrical resistance of which varies progressively with strain. A calibrated piece of the material is bonded to the component to be monitored, and its change in resistance provides a measure of strain.

Resistance Welding

A group of welding processes that produce coalescence of metals with resistance heating and pressure. See also *flash welding*, *projection welding*, *resistance seam welding*, and *resistance spot welding*.

Resistance Welding Die

The part of a resistance welding machine, usually shaped to the work contour, in which the parts being welded are held and which conducts the welding current.

Resistance Welding Electrode

The part or parts of a resistance welding machine through which the welding current and, in most cases, pressure is applied directly to the workpiece. The electrode may be in the form of a rotating wheel, rotating roll, bar, cylinder, plate, clamp, chuck, or modification thereof.

Resistance Welding Gun

A manipulating device to transfer current and provide electrode force to the weld area (usually in reference to a portable gun).

Resistivity

Resistance to the passage of electricity. It is the reciprocal of conduction and in the S.I. system, is measured in micro ohm centimeters. See *electrical resistivity*.

Resite

Synonym for *C-stage*.

Resitol

Synonym for *B-stage*.

Resol

Synonym for *A-stage*.

Resole Resin

Linear phenolic resin produced by alkaline condensate of phenol and formaldehyde.

Resolution

The capacity of an optical or radiation system to separate closely spaced forms or entities; in addition, the degree to which such forms or entities can be discriminated. Resolution is usually

specified as the minimum distance by which two lines or points in the object must be separated before they can be revealed as separate lines or points in the image. See also *resolving power* and *shape resolution*.

Resolving Power

(1) The ability of a given optical lens system to reveal fine detail and an object. Of a microscope or individual lens, the size of the smallest feature that can be distinguished. It is about 0.2 μm in a conventional light microscope. See also *resolution*.

Resonance

The excitation of a component or system at its natural frequency of vibration. Such excitation can induce a progressive increase in amplitude of vibration with associated increase in stress and consequent risk of fatigue failure.

Resonant Forced Vibration Technique

A technique for performing dynamic mechanical measurements on plastics, in which the sample is oscillated mechanically at the natural resonant frequency of the system. The amplitude of oscillation is maintained constant by the addition of makeup energy. Elastic modulus is calculated from the measured frequency. Damping is calculated from the additional energy required to maintain constant amplitude.

Resorcinol

A colorless crystalline material with a melting point of 230°F (110°C). It is very soluble in water and in alcohol. It is used in the production of plastics; in the manufacture of fluorescein; in the production of xanthene and azo dyes, particularly the fast *Alsace green*; in medicine as an antiseptic; and in making the explosive lead styphnate. Resorcinol polymerizes with formaldehyde to form the *resorcinol-formaldehyde plastics* that will cure at room temperature and with only slight pressure. They are used in strong adhesives for plywood and wood products and do not deteriorate from acid action as some other plastics do. *Resorcinol adhesives* remain water soluble during the working period for 2–4 h and are then insoluble and chemical resistant.

Response Curve for *N* Cycles

In fatigue data analysis, a curve fitted to observed values of percentage survival at *N* cycles for several stress levels, where *N* is a preassigned numbers such as 10^6 and 10^7 . It is an estimate of the relationship between applied stress and the percentage of the population that would survive *N* cycles. See also *S–N curve*.

Rest Periods

With reference to fatigue, periods of significant length during which cyclic loading is suspended and some recovery may occur with consequent benefit to fatigue life.

Rest Potential

See *corrosion potential* and *open-circuit potential*.

Restrained Weld Test

A test in which the test piece being welded is firmly secured by some support system of bolts or substantial preliminary welds to minimize movement during the test welding cycle. The restraint imposes high tensile stresses as a result of weld metal contraction during cooling following welding. The test, therefore, indicates the likelihood of cracking being encountered when welds in a similar procedure are made during production.

Restraint

Any external mechanical force that prevents a part from moving to accommodate changes in dimension due to thermal expansion or contraction. Often applied to weldments made while clamped in a fixture. Compare with *constraint*.

Restrictor Rings

Rings, usually faced with *white metal*, placed outside a bearing to prevent fluid from being discharged.

Restrike

(1) A repeat of a forging or stamping operation to improve dimensions or quality of surface detail. (2) Additional compacting of a sintered powder metallurgy compact.

Restriking

(1) The striking of a trimmed but slightly misaligned or otherwise faulty forging with one or more blows to improve alignment, improve surface condition, maintain close tolerances, increase hardness, or affect other improvements. (2) A *sizing* operation in which coining or stretching is used to correct or alter profiles and to counteract distortion. (3) A salvage operation following a primary forging operation in which the parts involved are rehit in the same forging die in which the pieces were last forged.

Resultant Field

The magnetic field that is the result of two or more magnetizing forces impressed on the same area of a magnetizable object. Sometimes called a vector field.

Resultant Rake

The angle between the tooth face and an axial plane through which the tooth point measured in a plane perpendicular to the cutting edge. The resultant rake of a cutter is a function of three other angles: radial rake, axial rake, and corner angle.

Retained Austenite

See *steel*.

Retainer

See *cage*.

Retardation Plate

A plate placed in the path of a beam of polarized light in an *optical microscope* for the purpose of introducing a difference in phase. Usually, quarter-wave or half-wave plates are used, but if the light passes through them twice, the phase difference is doubled.

Retarder

Synonym for *inhibitor*.

Retention Time (t_R)

In *chromatography*, the amount of time a sample compound spends in the chromatographic column.

Retentivity

The capacity of a material to retain a portion of the magnetic field set up in it after the magnetizing force has been removed.

Retort

A vessel used for distillation of volatile materials, as in separation of some metals and in destructive distillation of coal.

Retrogradation

A change of starch pastes that are used in adhesive formulations from low to high consistency upon aging.

Retrogression

The phenomenon observed in the precipitation hardening of solution treated material whereby initial heat treatment at some low aging temperatures subsequently causes, at some higher temperature a more rapid hardening than normal and a consequent risk of over aging. See *precipitation hardening*.

Reverberatory Furnace

A furnace in which the flame used for melting the metal does not impinge on the metal surface itself but is reflected off the walls of the roof of the furnace. The metal is actually melted by the generation of heat from the walls and the roof of the furnace. Although this furnace heating concept is still used in many foundries and smelters, more modern reverberatory furnaces use roof burners or side burners directed toward the metal surface. Such furnaces are designed in either the wet hearth or dry hearth configuration. In a wet hearth furnace, the products of combustion are in direct contact with the top of the molten bath, and the heat transfer is achieved by a combination of convection and radiation. In a dry hearth furnace, the charge of solid metal is positioned on a sloping hearth above the level of the molten metal so that the charge is completely enveloped by the hot gases. Heat is rapidly absorbed by the solid charge, which melts and subsequently drains from the sloping hearth into the wet holding basin or chamber.

Reverse Drawing

Redrawing of a sheet metal part in a direction opposite to that of the original drawing.

R

Reverse Engineering

The practice of copying a design by measuring and analyzing a sample, repairing drawings, specification and procedures, and producing the copy without infringing the original manufacturers rights. The legal aspects require great care.

Reverse Flange

A sheet metal flange made by shrinking, as opposed to one form by stretching.

Reverse Flow Forging

Processes in which a billet contained in a die is partially pierced by a RAM causing it to expand to fill the die and extrude back around and up the ram. Impact extrusion is similar but utilizes a high-velocity ram.

Reverse Helical Winding

In *filament winding*, as the fiber delivery arm traverses one circuit, a continuous helix is laid down, reversing direction at the polar ends, in contrast to biaxial, compact, or sequential winding. The fibers cross each other at definite equators, the number depending on the helix. The minimum region of crossover is three. See also the term *helical winding*.

Reverse Impact Test

A test in which one side of a sheet of plastic is struck by a pendulum or falling object, and the reverse side is inspected for damage.

Reverse Polarity

Direct-current arc welding circuit arrangement in which the electrode is connected to the positive terminal. A synonym for *direct current electrode positive (DCEP)*. Contrast with *straight polarity*.

Reverse Redrawing

A second drawing operation in a direction opposite to that of the original drawing.

Reverse(d) Polarity (Welding)

An ambiguous term as is its opposite, *straight polarity*. In some countries, including the United Kingdom, reversed polarity usually means direct current arc welding with the electrode connected to the negative pole of the supply and straight polarity has the electrode connected to the positive. Unfortunately, U.S. terminology is exactly opposite. Better terms are *electrode positive* and *electrode negative*.

Reverse-Current Cleaning

Electrolytic cleaning in which a current is passed between electrodes through a solution, and the part is set up as the anode. Also called *anodic cleaning*.

Reversed Stress

A cyclic stress where the compressive load and the tensile load are of the same value. See *fatigue*.

Reversed-Phase Chromatography (RPC)

Bonded-phase chromatography with a nonpolar stationary phase and a polar mobile phase. See also *bonded-phase chromatography*.

Reversible (Electrolytic) Cell

A cell in which the two electrodes are immersed in separate electrolytes and in which reversing the current flow results in a reversion of the reactions at the electrodes.

Reversing Mill

A rolling mill through which the product passes backward and forward a number of times, the direction of rotation of the rolls reversing on each pass.

Reversion

Generally the return to some previous condition. More specifically, the reversal of a martensite shear transformation in nonferrous alloys to restore precisely the structure of the original pre-quenched phase.

Reworked Plastic

A thermoplastic that is reground, pelletized, or solvated after having been previously processed by molding, extrusion, and so forth. In many specifications, the use of reworked material is limited to clean plastic that meets the requirements specified for virgin material and yields a product essentially equal in quality to one made from virgin material only.

Reyn

The former English unit of dynamic viscosity equal to approximately 14.9 poise.

Reynold's Equation

A basic equation of *hydrodynamic lubrication*.

R.F. Radio Frequency

As in R.F. welding that utilizes a R.F. power beam for radiation heating.

RGA

See *residual gas analysis*.

Rhenium and Alloys

Rhenium (symbol Re) is a rare, silvery-white element with a metallic luster. It is one of the hardest metals at 580 HV (30% cold work), is one of the heaviest with the density of 21 g/cm³, and has one of the highest melting points at 5760°C. It also has no known ductile to brittle transition temperature, which enables rhenium parts to be thermally cycled without being degraded. It remains strong at high temperatures and does not become brittle after welding. Although it is a very ductile material, it has the third highest modulus of elasticity of any metal. The addition of rhenium to molybdenum and tungsten has enhanced their strength, ductility, and formability.

The crystal structure is closely packed hexagonal, making it more difficult to work than the cubic-structured tungsten, but the crystal grains are tiny, and small amounts of rhenium added to tungsten improve ductility and increase high-temperature strength of tungsten used in lamp filaments and wire.

During the past decade, interest has increased dramatically in rhenium as a construction material for parts with complex shapes in high-temperature service environments. A typical example of such an application is rocket thrusters, which have operating temperatures up to 2230°C. Other applications include welding rods, thermocouples, and cryogenic magnets. When rhenium is added to superalloys in amounts of 3%–6%, the turbine-inlet temperature in gas turbine engines is increased by 125°C.

Processing

The primary source of rhenium is the by-product molybdenite obtained from porphyry copper deposits.

Virtually, all of the wrought products of pure rhenium are produced from bars made by powder metallurgy. Although rhenium can be arc melted in an inert atmosphere, the resultant metal is not well suited for fabrication due to the coarse as-melted grain size and the possible segregation of small amounts of rhenium oxide at the grain boundaries. Even with vacuum melting, the workability has not equaled that of bars produced by powder metallurgy. The latter bars have a small grain size and are much more amenable to fabrication.

Rhenium powder produced by hydrogen reduction of ammonium perrhenate is consolidated by pressing and split rectangular dies at pressures of 25–30 tsi using nonlubricated powder. These press bars or vacuum pre-sintered at 1200°C and a pressure of 0.5–1 μ . They are subsequently resistance-sintered in dry hydrogen adding maximum temperature of approximately 90% of the melting point in a manner almost identical to that used for tungsten. The sintered bars are normally 90%–96% of the theoretical density, having undergone 15%–20% shrinkage in each dimension. These bars are then ready for fabrication.

Pure rhenium is fabricated by cold working with frequent intermediate recrystallizing anneals. Hot working of rhenium results in “hot short” failures, probably because of the presence of rhenium heptoxide at the grain boundaries. This volatile oxide has a melting point of 297°C and a boiling point of 363°C.

The fabrication of rhenium wire requires processing by swaging and drawing. Work hardening is so great in cold swaging that reductions are limited to one 10% reduction between anneals to avoid serious damage to the swaging dies. The reductions are somewhat greater in cold drawing beginning with 10% but increasing to about 40% between anneals. Diamond drawing dies are used for all pure rhenium wire drawing.

The production of rhenium strip is likewise accomplished by cold rolling. After several light initial reductions on the sintered bars, reductions up to 40% can be affected between anneals. Strip thinner than 0.13 mm is rolled using small-diameter tungsten carbide work roles in a “4 high” mill. Strip can be processed in this manner to thicknesses of 0.03 mm.

Because of the rapid rate of work hardening that accompanies the cold working of rhenium, annealing constitutes a very important part of the fabrication processes. Frequent anneals are necessary at temperatures of 1550°C–1700°C for times varying from 10 to 30 min in an atmosphere of dry hydrogen or a hydrogen–nitrogen mixture. Furnaces utilizing molybdenum heating elements and aluminum oxide refractories are used most extensively. Anneals performed as indicated result in complete recrystallization with the

grain size usually between 0.010 and 0.040 mm and a hardness of about 250–275 VHN.

It is virtually impossible to apply conventional ingot casting and hot/warm forming techniques to rhenium because of its high melting point, poor oxidation resistance, and the difficulty of working an as-cast structure.

Rhenium and its alloys are generally manufactured in the United States and Europe through the powder-metallurgy route, with a tolerance on the rhenium addition in the range of $\pm 0.5\%$ or better. Various methods have been chosen to suppress second-phase formation. In Russia, vacuum melting is the preferred production process for alloys such as Mo-47% Re and W-27% Re, which have rhenium content tolerances of $\pm 0.3\%$.

In alloys W-3%–5% Re for wire products, the tungsten-based material is intentionally doped with potassium, aluminum, and silicon to control recrystallization behavior. European and Russian companies also manufacture wire of these alloys in the undoped condition. In recent years, W-3% to 5% Re and up to 10% Re undoped compositions have been found to be ideal for fabricating x-ray targets, heat sinks, and other complex shapes.

Better performance can be achieved by additions of 11%–14% rhenium to molybdenum and additions of 10%, 15%, and 20% rhenium to tungsten, as so-called dilute or moderate alloys, Mo-41%–44% Re is the basis of another group of alloys for consideration.

Properties

Rhenium is a refractory metal with properties similar in many ways to tungsten and molybdenum. Pure rhenium has significantly greater room-temperature ductility combined with good high-temperature strength. When used as an alloy addition with tungsten or molybdenum forming body-centered cubic solid solutions, rhenium produces significant improvements in the ductility of those metals.

It is significant to note that the melting point of rhenium is the second highest of the metals, exceeded only by tungsten. Its density is surpassed only by osmium, iridium, and platinum and its modulus of elasticity only by osmium and iridium. Moreover, the hardness and strength of rhenium are very high, and its rate of work hardening is greater than that for any other metal.

The combination of high strength and ductility exhibited by rhenium and rhenium alloys is of great interest. Furthermore, these materials can be inert gas-arc-welded with a resultant weld that is ductile and possesses corrosion resistance as good as the parent metal. Note ductile-to-brittle transition is observed in pure rhenium or the rhenium–molybdenum alloys containing 30–50 wt.% Re as occurs in molybdenum at about room temperature and in tungsten at approximately 300°C. Although rhenium editions lower the transition temperature of tungsten, it still occurs above room temperature. However, even below the transition temperature for the recrystallized material, the ductility of the rhenium–tungsten alloys is higher than that of pure tungsten.

Fabrication

Rhenium cannot be machined by conventional methods because it work-hardens rapidly. However, electrical discharge machining is an effective manufacturing method, and parts can be brought to final finish through ceramic or diamond grinding. Rhenium can be plastically cold formed, although frequent annealings are required to restore formability after relatively small deformation.

Chemical vapor deposition is also a practical method for fabricating rhenium components with complex shapes. This method is particularly advantageous for products with thin metal structures,

R

and for applications that require an oxidation-resistant protective layer on the rhenium surface. In addition, recently developed multi-form powder-metallurgy products have the advantage of being isotropic, and they can be produced with a high relative density and consistent mechanical properties from lot to lot by well-established technologies.

Thermal spray is another alternative to the conventional powder-metallurgy route. Specifically, the cold gas dynamic spray method (CGSM) compacts rhenium powder as a coating onto a suitable substrate by ballistic impingement. Unfortunately, little success has been achieved because of the morphology and small particle size of rhenium metal powder.

Low-pressure plasma spray (LPPS) experiments have produced tantalum forms with thickness of 6 mm and a relative density exceeding 95%. These experiments indicate that LPPS may be a realistic way to produce near-net shape components of refractory metals, including rhenium. A preliminary attempt to make rhenium tubing resulted in a relative density of 83.5%, which was increased to over 95% after sintering. The prospects for manufacturing high-density isotropic products by plasma spraying of rhenium appear to be very good, although it is difficult to produce rhenium powder with good flow properties.

Among the newest technologies, the directed light fabrication (DLF) process is a multidimensional, laser-controlled deposition technique. Good results in casting complex near-net shape products have been achieved for metals with moderate melting points. The unidirectional solidification of a small molten pool makes this a single-step, almost waste-free process without risk of oxidation. Further studies of the DLF process are encouraged to develop the processing technique for refractory metals and to study the final properties of its products.

A long-standing effort has been made to apply the favorable combination of mechanical properties (high strength, outstanding plasticity, and formability) exhibited by rhenium at ambient temperature to pressure-shape the required profile from semifinished products such as sheet. Rhenium tube-spinning technology has recently emerged from being only a developmental effort.

Another example is the trend toward adopting explosive metalworking techniques for joining in fabricating rhenium parts. However, because rhenium work-hardens extraordinarily fast at low levels of cold deformation, frequent intermediate annealing constitutes a major and important part of such fabrication processes. As an interesting alternative, the appropriate shape design has been achieved by winding rhenium wire in layers, and filling the interwire void space with fine-grain particles by chemical vapor deposition.

Direct hot isostatic pressing (HIP) of near-net shape rhenium products is an intense plastic-deforming technique applied to powder that has not been explored in much detail. Limited data has been published on the effect of HIP on material properties of rhenium powder-metallurgy ingots and mill products. It is known that a combination of sintering and HIP procedures has demonstrated the possibility of developing both high density and good formability in powder-metallurgy rhenium parts obtained after further machining.

One of the challenges with direct HIP consolidation of near-net geometry is to reach near-full density of rhenium at temperatures far below typical sintering temperatures. During the development of the technique, careful evaluation of process parameters such as pressure, temperature, time, and heating/cooling rates may make it possible to control grain size, material properties, and dimensional variations. Because of the need to control so many parameters, success may depend on the nascent technology of intelligent HIP, in which the response of the material to processing parameters dictates the selection of optimal processing conditions.

Applications

The outstanding properties of rhenium and rhenium alloys suggest their use in many specialized applications.

Thermocouples

Rhenium versus tungsten thermocouples can be used for temperature measurement and control to approximately 2200°C, whereas previous thermocouple use was limited to temperatures below 1750°C. Indeed, 74% W–26% Re versus W thermocouples can be used at temperatures of at least 2750°C with a high emf output ensuring accurate precise temperature measurements with excellent reproducibility and reliability.

Electronic

Rhenium is now widely used for filaments for many spectrographs and for ion gauges for measuring high vacuum. Its ductility, chemical properties, including the fact that it does not react with carbon to form a carbide, and its emission characteristics make it superior to tungsten for these applications.

The elevated temperature properties of rhenium and rhenium alloys, their weldability, and electrical resistivity suggest their use for various components in electronic tubes.

Electrical

The superconducting properties of Re–Mo alloys have prompted their use for coils in compact-size electromagnets with high field strength. Although this application is still in the development stages, it looks most promising.

Rhenium has received considerable acclaim as an electrical contact material. It possesses excellent resistance to wear as well as arc erosion. Furthermore, the contact resistance of rhenium is extremely stable because of its good corrosion resistance in addition to the fact that possible formation of an oxide film on the contacts would not cause any appreciable change in the contact resistance since the resistivity of the oxide is almost the same as that of the metal. Extensive tests for some types of make-and-break switching contacts has shown rhenium to have 20 times the life of platinum–palladium contacts currently in use.

Heating elements for resistance heated vacuum or inert atmosphere furnaces seems to be a potential application for rhenium and especially rhenium–tungsten alloys. These materials would not undergo the embrittlement that occurs in tungsten upon heating, and they would allow for usage in vacuum, hydrogen, or inert atmospheres.

Welding Filler Rod

Rhenium and Re–Mo alloys can be readily welded. In fact, Re–Mo alloy can be used as a filler material for obtaining ductile welds in molybdenum. Although not all of the problems associated with the heat-affected zone are readily overcome, the properties of welds made with Re–Mo alloy filler wire are very much better.

Rheocasting

(1) Casting of a continuously stirred semisolid metal slurry. The process involves vigorous agitation of the melt during the early stages of solidification to break up solid dendrites into small spherulites. See also *semisolid metal forming*. (2) Diecasting or other processes utilizing the thixotropic characteristics of stirred, partially solidified alloys. When a partly solidified alloy is stirred, the

normal dendritic structure breaks down to form a slurry of rounded particles. In practice, the slurry contains little liquid, but it becomes increasingly fluid the more vigorously it is stirred. In the real casting process, the highly fluid slurry is fed into the shot sleeve of a pressure diecasting machine and injected into the die. *Thixocasting* is a related process in which rapidly cooled slugs of rheocast slurry are held at an intermediate temperature prior to reheating and injection. In **thixoforging**, the rapidly cooled rheocast slugs are forged in closed dies. Benefits claimed for rheocasting include lower injection temperature leading to reductions in die wear, energy costs, process cycle time, shrinkage and porosity, and a capability to maintain high quality in thin sections. See also *rheoforging*.

Rheodynamic Lubrication

A regime of lubrication in which the rheological (non-Newtonian) properties of the lubricant predominate. This term is especially applied to lubrication with grease.

Rheology

(1) The study of the interaction of time, temperature, and stress on the properties and characteristics of materials. The term is usually used in connection with noncrystalline materials such as glass, plastic, and rubbers but aspects are relevant to the creep of metals and also note **rheocasting**. (2) The science of deformation and the flow of matter.

Rheoplectic Material

A material that shows an increase in viscosity with time under a constant shear stress. After removal of the shear stress, the viscosity slowly returns to its original level. Compare with *thixotropy*.

Rheotropic Brittleness

That portion of the brittleness characteristic of non-face-centered cubic metals, where tested in the presence of a stress concentration or at low temperatures or high strain rates, that may be eliminated by prestraining under milder conditions.

Rhodanizing

Electroplating with rhodium.

Rhodium

Metallic rhodium is the whitest of the platinum metals and does not tarnish under atmospheric conditions. This rare metal (symbol Rh), found in platinum ores, is very hard and is one of the most infusible of the metals. The melting point is 1963°C. It is insoluble in most acids, including aqua regia but is attacked by chlorine at elevated temperatures and by hot fuming sulfuric acid. Liquid rhodium dissolves oxygen, and ingots are made by argon-arc melting. At temperatures above 1200°C, rhodium reacts with oxygen to form rhodium oxide, Rh₂O₃. The specific gravity is 12.44. Rhodium is used to make the nibs of writing pens, to make resistance windings in high-temperature furnaces, for high-temperature thermocouples, as a catalyst, and for laboratory dishes. It is the hardest of the platinum group metals; the annealed metal has a Brinell hardness of 135. Rhodium also has considerable strength and rigidity, ultimate tensile strengths ranging from 952 to 2068 MPa, and tensile modulus from 28.9×10^4

to 37.9×10^4 MPa, depending on condition or hardness. Rhodium is also valued for electroplating jewelry, electric contacts, hospital and surgical instruments, and especially reflectors.

The most important alloys of rhodium are rhodium–platinum. They form solid solutions in any proportion, but alloys of more than 40% rhodium are rare. Rhodium is not a potent hardener of platinum but increases its high-temperature strength. It is easily workable and does not tarnish or oxidize at high temperatures. These alloys are used for thermocouples and in the glass industry.

Rhombohedral

Having three equal axes, with the included angles equal to each other, but not equal to 90°. See also the term *unit cell*.

Rib (Metals)

(1) A long V-shaped or radiused as indentation used to strengthen large sheet metal panels. (2) A long, usually thin protuberance is used to provide flexural strength to a forging (as in a rib-web forging).

Rib (Plastics)

A reinforcing member designed into a plastic part to provide lateral, horizontal, loop, or other structural support.

Rib Mark

A curved line on the crack surface of ceramics or glasses, usually convex in the general direction toward which the crack is running. The term is useful in referring to a mark of the shape until its specific nature is learned.

Riddle

A sieve used to separate foundry sand or other granular materials into various particle-size grades or to free such a material of undesirable foreign matter.

Ridging Wear

A deep form of scratching in parallel ridges usually caused by plastic flow of the subsurface layer.

Rifled Bore

Spiral ridges, grooves, or undulations deliberately introduced along the bore of tubes. In gun barrels, they spin and stabilize the shot. In tubes for heat exchangers, they cause the contents to swirl giving enhanced heat transfer capacity and reducing the possibility of hot spots and steam blanketing.

Rig Testing

Test of structures or components of assemblies intended to simulate service environments, usually on a large scale.

Rigging

The engineering design, layout, and fabrication of pattern equipment for producing castings, including a study of the casting solidification program, feeding and gating, risering, skimmers, and fitting flasks.

R

Right-Hand Cutting Tool

A cutter all of whose flutes twist away in a clockwise direction when viewed from either end.

Rightward Welding

See *backhand welding*.

Rigid Plastics

For purposes of general classification, a plastic that has a modulus of elasticity either in flexure or in tension greater than 690 MPa (100 ksi) at 23°C (73°F) and 50% relative humidity.

Rigid Resin

A resin having a modulus high enough to be of practical importance, for example, ≥ 690 MPa (100 ksi).

RIM

See *reaction injection molding*.

Rimmed Steel

A low-carbon steel that is only partially deoxidized before pouring. As a result, on solidification some of the carbon in the steel reacts with the remaining oxygen to form carbon dioxide. This occurs fairly early during solidification, so the material forming the outer layers at the sides and bottom of the ingot tends to be lower in carbon and impurities than the interior. Also, a band of voids filled with carbon dioxide develops at about one-third the radius measured from the exterior. There is a concentration of impurities at the center line, but, because the volume of voids approximately balances the shrinkage, the central shrinkage pipe is small. During rolling, the voids collapse and fuse. The final product has a high-purity surface layer, which is particularly suitable for sheet of good surface quality and corrosion resistance. See the term *capped steel*.

Ring and Circle Shear

A cutting or shearing machine with two rotary-disk cutters driven in unison and equipped with a circle attachment for cutting inside circles or rings from sheet metal, where it is impossible to start the cut at the edge of the sheet. One cutter shaft is inclined to the other to provide cutting clearance so that the outside section remains flat and usable. See also *circle shear* and *rotary shear*.

Ring Riser

A *riser block* with openings matching those in the metal forming.

Ring Rolling

The process of shaping weldless rings from pierced disks or shaping thick-wall ring-shaped blanks between rolls that control wall thickness, ring diameter, height, and contour. See the term *axial rolls*.

Ring Seal

A piston ring-type seal that assumes its sealing position under the pressure of the fluid to be sealed.

Ring Tests

Various tests of welding characteristics in which a circular disc, hole, or groove are welded and checked for cracking.

Ringing

The audible or ultrasonic tone produced in a mechanical part by shock, and having the natural frequency or frequencies of the part. The quality, amplitude, or decay rate of the tone may sometimes be used to indicate the quality or soundness. A crude crack detection test. See also *sonic testing* and *ultrasonic testing*.

Rinsability

The relative ease with which a substance can be removed from a metal surface with a liquid such as water.

Ripple Formation

Formation of periodic ridges and valleys transverse to the direction of motion on a solid surface. Also referred to as *rippling*.

Ripple Mark

See *Wallner lines* (ceramics and glasses).

Rise Time

In urethane foam molding, the time between the pouring of the urethane mix and the completion of foaming.

Riser

(1) A reservoir of molten metal connected to a casting to provide additional metal to the casting, required as a result of shrinkage before and during solidification. (2) That section of pipeline extending from the ocean floor up the offshore oil-drilling platform. Also the vertical tube in a steam generator convection bank that circulates water and steam upward.

Riser Blocks

(1) Plates or pieces inserted between the top of a metal forming press bed or bolster and the die to decrease the height of the die space. (2) Spacers placed between bed and housings to increase *shut height* on a four-piece tie-rod straight-side press.

River Lines/Pattern

Steps on a cleavage fracture surface that radiate from the origin.

River Marks (Ceramics and Glasses)

Cleavage steps on individual grains of a polycrystalline material or on a single crystal. These markings spread out away from the point of origin. These are a special case of *twist hackle*.

River Pattern (Metals)

A term used in fractography to describe a characteristic pattern of cleavage steps running parallel to the local direction of crack propagation on the fracture surfaces of grains that have separated by cleavage.

Rivet

A rivet is a short rod with a head formed on one end. A rivet is inserted through aligned holes in two or more parts to be joined; then by pressing the protruding end, a second head is formed to hold the parts together permanently. The first is called the manufactured head and the second the point. In forming the point, a hold-on or dolly bar is used to back up the manufactured head and a rivet is driven, preferably by a machine riveter. For high-grade work such as boiler-joint riveting, the rivet holes are drilled and reamed to size, and a rivet is driven to fill the hole completely. Structural riveting uses punched holes.

Small rivets (11 mm and under) are for general-purpose work with head forms as follows: flat, countersunk, button, pan, and truss. These rivets are commonly made of rivet steel, although aluminum and copper are used for some applications. The fillet under the head may be up to 0.8 mm in radius.

Large rivets (13 mm and over) are used for structural work and in boiler and ship construction with heads as follows: roundtop countersunk, button (most common), high button or acorn, pan, cone (truncated), and flattop countersunk.

Boiler rivets have heads similar to large rivets with steeple (conical) added but have different proportions from large rivet heads in some cases.

Special-purpose rivets are tinner's rivets, which have flatheads for use in sheet metal work; cooper's rivets, which are used for riveting hoops for barrels, casks, and kegs; and belt rivets, use for joining belt ends.

Blind rivets are special rivets that can be set without access to the point. They are available in many designs but are of three general types: screw, mandrel, and explosive. In the mandrel type, the rivet is set as the mandrel is pulled through. In the explosive type, an explosive charge in the point is set off by a special hot iron; the explosion expands the point and sets the rivet.

Standard material for rivets in open-hearth steel (containing manganese, phosphorus, and sulfur) with tensile strengths of 310–380 MPa. Standards include acceptance tests for cold and hot ductility and hardness. Materials for some special-purpose rivets are aluminum and copper. In the past four decades, aluminum and titanium rivets have been used in the aerospace industry very effectively.

Riveting

Joining of two or more members of a structure by means of metal rivets, the unheaded end being upset after the rivet is in place.

Roasting

Heating an ore to affect more chemical change that will facilitate *smelting*.

Robber

An extra cathode or cathode extension that reduces the current density on what would otherwise be a high-current-density area on work being electroplated.

Robotics

Robotics is the field of engineering concerned with the development and application of robots, as well as computer systems for their control, sensory feedback, and information processing. There are many types of robotic devices, including robotic manipulators, robot hands, mobile robots, walking robots, aids for disabled persons, telerobots, and microelectromechanical systems (*MEMS*).

The term *robotics* has been very broadly interpreted. It includes research and engineering activities involving the design and development of robotic systems. Planning for the use of industrial robots in manufacturing or evaluation of the economic impact of robotic automation can also be viewed as robotics. This breadth of usage arises from the interdisciplinary nature of robotics, a field involving mechanisms, computers, control systems, actuators, and software.

Robotic Mechanisms

Robots produce mechanical motion that, in most cases, results in manipulation or locomotion. For example, industrial robots manipulate parts or tools to perform manufacturing tasks such as material handling, welding, spray painting, or assembly; automated guided vehicles are used for transport of materials in factories and warehouses. Telerobotic mechanisms provide astronauts with a large manipulator for space applications. Walking machines have applications in hazardous environments. Mechanical characteristics for robotic mechanisms include degrees of freedom of movement, size and shape of the operating space, stiffness and strength of the structure, lifting capacity, velocity, and acceleration under load. Performance measures include repeatability and accuracy of positioning, speed, and freedom from vibration.

Manipulator Geometries

An important design for robotic manipulators is the articulated arm, a disfiguration with rotary joints that resembles a human arm. An extension of this idea is the selective compliance assembly robot arm (SCARA) configuration, which is been extensively applied to the assembly in manufacturing. Manipulators with this configuration have high stiffness during vertical motions. Cylindrical configurations with a Rotary joint at the base and a prismatic joint at the shoulder are useful for simple material transfer and assembly. Overhead gantry (Cartesian) robots are used for high-payload applications and those requiring rapid positioning over large workspaces.

Degrees of Freedom

Some manipulators have simple mechanical designs involving only two or three degrees of freedom of movement. Most robotic manipulators, however, have at least six degrees of freedom so that the device position a part or approach a part with any desired position or orientation. The wrist is positioned that any x , y , z position in the workspace. Then, the end effector is rotated to a desired orientation (roll, pitch, yaw). In effect, the wrist represents the origin of a three-axis coordinate fixed to the gripper. Moving the first three points of the arm translates this origin to any point in a three-axis coordinate system fixed to the work space; motion of the final three joints (in the wrist) orients the gripper coordinate system in rotation about an origin at the wrist point. Some robots have wrist joint axes that do not intersect at a single point. However, the mathematics of mechanical motion (kinematics) is considerably simplified if these axes do intersect at a point.

R

Types of Joints

Robotic mechanisms can have joints that are prismatic (linear motion), articulated (rotary motion), or a combination of both types. Although many robots use only articulated joints to imitate the human arm, limited actions can be produced by using prismatic joints alone. Robot locomotion can also be obtained by the use of wheels and treads. Walking robots that use articulated legs have been developed.

Joint Actuators

Actuators for moving joints of a robotic mechanism are typically electric or hydraulic motor. Although actuators can be placed directly at the joints, the weight and bulk of these motors and associated gear transmissions limit the performance of the robot, particularly at the wrist of industrial robots. Another design involves placement of the actuators in the base of the robot and transmission of motion to the joints through mechanical linkages such as shafts, belts, cables, or gears. This approach overcomes many of the problems associated with locating actuators at the joints but requires the design of backlash-free mechanical linkages that can transmit power effectively through the arm in all of its positions and orientations. Other devices include end effectors, robotic hands, and mobile robots.

Rochelle Copper

(1) A copper electrodeposit obtained from copper cyanide plating solution to which Rochelle salt (sodium potassium tartrate) has been added for grain refinement, better anode corrosion, and cathode efficiency. (2) The solution from which a Rochelle copper electrodeposit is obtained.

Rock Candy Fracture

A fracture that exhibits separated-grain facets; most often used to describe an *intergranular fracture* in a large-grained metal.

Rocking Curve

A method used in *x-ray topography* for determining the degree of imperfection in a crystal by using monochromatic, collimated x-rays reflecting off a “perfect” crystal to probe a second test crystal. A rocking curve is obtained by monitoring the x-ray intensity diffracted by the test crystal as it is slowly rocked or rotated, through the Bragg angle for the reflecting planes.

Rocking Shear

A type of guillotine shear that utilizes a curved blade to shear sheet metal progressively from side to side by a rocker motion.

Rockrite Tube-Reducing Process

See *tube reducing*.

Rockwell Hardness Number

A number derived from the net increase in the depth of impression as the load on an indenter is increased from a fixed minor load to a major load and then returned to the minor load. Various scales

of Rockwell hardness numbers have been developed based on the hardness of the materials to be evaluated. The scales are designated by alphabetic suffixes to the hardness designation. For example, 64 HRC represents the Rockwell hardness number of 64 on the Rockwell C scale. See also *Rockwell superficial hardness number*.

Rockwell Hardness Test

An indentation hardness test using a calibrated machine that utilizes the depth of indentation, under constant load, as a measure of hardness. Either a 120° diamond cone with a slightly rounded point or a 1.6 or 3.2 mm (1/16 or 1/8 in.) diameter steel ball is used as the indenter. See also *Brale indenter*.

Rockwell Superficial Hardness Number

Like the *Rockwell hardness number*, the superficial Rockwell number is expressed by the symbol HR followed by a scale designation. For example, 81 HR 30N represents the Rockwell superficial hardness number of 81 on the Rockwell 30N scale.

Rockwell Superficial Hardness Test

The same test as used to determine the Rockwell hardness number except that smaller minor and major loads are used. In Rockwell testing, the minor load is 10 kgf, and the major load is 60, 100, or 150 kgf. In superficial Rockwell testing, the minor load is 3 kgf, and major loads are 15, 30, or 45 kgf. In both tests, the indenter may be either a diamond cone or a steel ball, depending principally on the characteristics of the material being tested.

Rod

A solid round metal section 9.5 mm (3/8 in.) or greater in diameter, whose length is great in relation to its diameter.

Rod Mill

(1) A *hot mill* for rolling rod. (2) A mill for fine grinding, somewhat similar to a *ball mill*, but employing long steel rods instead of balls to affect grinding.

Roke

A planar defect penetrating from a surface, due to oxide entrapment during casting.

Roll Bending

Curving sheets, bars, and sections by means of rolls. See the term *bending rolls*.

Roll Compacting

Progressive compacting of metal powders by use of a rolling mill.

Roll Flattening

The flattening of metal sheets that have been rolled in packs by passing them separately through a two-high cold mill with virtually no deformation. Not to be confused with *roller leveling*.

Roll Forging

A process of shaping stock between two driven rolls that rotate in opposite directions and have one or more matching sets of grooves in the rolls; used to produce finished parts or preforms for subsequent forging operations.

Roll Forming

(1) Metal forming through the use of power-driven rolls whose contour determines the shape of the product; sometimes used to denote power *spinning*. (2) A process in which a series of powered rolls progressively shape material usually strip, to some relatively complex configuration, for example, tubes of various shapes that may subsequently be seam welded.

Roll Resistance Spot Welding

Process for making separated resistance spot welds with one or more rotating circular electrodes. The rotation of the electrodes may or may not be stopped during the making of a weld.

Roll Scale

The scale formed on hot rolled material.

Roll Straightening

The straightening of metal stock of various shapes by passing it through a series of staggered rolls, the rolls usually being in horizontal and vertical planes or by reeling in two-roll straightening machines.

Roll Table

A conveyor table where rolls furnish the contact surface.

Roll Threading

See preferred term *thread rolling*.

Roll Welding

Solid-state welding in which metals are heated, then welded together by applying pressure, with rolls, sufficient to cause deformation at the faying surfaces. The rolls forced together the component faces (a lap joint) or edges (a butt joint) producing a forge weld or pressure weld at the interface. See also *forge welding*.

Rolled Compact

A compact made by passing metal powder between rollers so as to form a relatively long, sheetlike compact.

Rolled Gold

Same as *gold filled* except that the proportion of gold alloy to the weight of the entire article may be less than 1/20th. Fineness of the gold alloy may not be less than 10 k. See also *karat*.

Rolled Sections

Bars rolled to form a wide variety of cross sections including I, H, L, and X.

Rolled Steel Joist (RSJ)

A steel beam of I and H cross section for load-bearing structural applications.

Roller Air Analyzer

An air-elutriation apparatus suitable for the particles size determination of the metal powders, especially in the subsieve range. See also *elutriation*.

Roller Bearing

(1) A bearing in which the relatively moving parts are separated by rollers. See the term *rolling-element bearing*. (2) A rolling-element bearing comprising inner and outer races, the gap between them being occupied by rollers. The rollers may be parallel or tapered and are usually contained in a cage.

Roller Expansion

A technique for expanding the bore of tubes. A ring of hardened rollers supported on a tapered mandrel is inserted into and rotated around the tube bore. As the rollers progress up the taper, they expand the bore. The technique is often used to secure tubes into tube plates or vessels and, with appropriate controls, strong and pressure tight joints can be achieved.

Roller Hearth Furnace

A modification of the pusher-type continuous furnace that provides for rollers in the hearth or muffle of the furnace whereby friction is greatly reduced and lightweight trays can be used repeatedly without risk of unacceptable distortion and damage to the work. See also *pusher furnace*.

Roller Leveler Breaks

Obvious transverse *breaks* usually about 3–6 mm (1/8–1/4 in.) apart caused by the sheet metal fluting during *roller leveling*. These will not be removed by stretching.

Roller Leveler Lines

Same as *leveler lines*.

Roller Leveling

(1) *Leveling* by passing flat sheet metal stock through a machine having a series of small-diameter staggered rolls that are adjusted to produce repeated reverse bending. (2) Processes for leveling sheet and straightening bar by passing the material through a series of staggered rolls. The first rollers induce a fairly severe bend and subsequent rollers apply bends of progressively reducing severity in alternate directions until the material emerges level/straight.

R

Roller Spot Welding

A resistance welding process in which a series of spot welds is produced in sheets traveling through a pair of rollers (discs would usually be a better description), which apply a driving and clamping force and deliver an intermittent electrical current of high amperage to cause welding. If the spot welds overlap, the process may be termed *seam welding*. If rotation of the rollers stops during the electrical supply, the processes may be termed “*step by step*.”

Roller Stamping Die

An engraved roller used for impressing designs and markings on sheet metal.

Roller Threading

A process for producing a thread form by forcing grooved roller dies against the bar being threaded. Compared to a cut thread, the roll threaded component is usually cheaper, slightly higher bulk strength, and contains compressive residual stresses at the surface, which can improve fatigue performance.

Rolling

The reduction of the cross-sectional area of metal stock, or the general shaping of metal products, through the use of rotating rolls. See also *rolling mills*.

Rolling (as in Surface Rolling)

A process in which a narrow roll bears heavily as it rolls against a component. The intention is to induce beneficial compressive residual stresses, which inhibits fatigue crack initiation. It is applied to features such as the radii of crankshafts.

Rolling (Pure Rolling with No Sliding and No Spin)

A motion of two relatively moving bodies, of opposite curvature, whose surface velocities in the common contact area are identical with regard to both magnitude and direction. See also *sliding* and *spin*. A process in which a bar, slab, etc. is reduced in cross section as it travels between a pair of rolls having a gap between them, which is smaller than the original thickness of the material. The rolls are usually driven, and tension may be applied to the material on the inlet or exit sides to assist or restrain its passage.

Rolling Angle

The angle between the line drawn through the working roll centers and the line drawn from one roll center to the point on the roll surface, which is first contacted by the material entering. Also termed *Angle of Bite*, *Nip (Angle)*, *contact angle*, and *similar variations*.

Rolling Direction (in Rolled Metals)

See *longitudinal direction*.

Rolling Element Bearing

A bearing in which the load between two components in relative motion is carried via rolling elements such as balls, rollers, or

needles. These rolling elements may bear directly onto the shaft or the housing, or they may bear on inner and outer *races* carried by the respective component. Compare with *plain bearing*.

Rolling Mandrel

In *ring rolling*, a vertical roll of sufficient diameter to accept various sizes of ring blanks and to exert rolling force on an axis parallel to the main roll. See also the term *axial rolls*.

Rolling Mill Equipment (or the Building Containing the Equipment)

Rolling, that is, reducing the cross section of bar, slab, sheet, etc., as it travels through the gap between a pair of rolls. Mills are described by a wide variety of terms. The simplest mills comprise only two rolls, other rolls have more, the total number being indicated by terms such as two-high, four-high, etc. A *Cluster Mill* or *Senzimer Mill* has six or more rolls. Some mills are reversing, that is the material is worked as it is passed through first in one direction and then in the other, the gap being reduced between passes. In a three high mill, all of the rolls are working rolls, that is, they reduce the material as it passes through one pair and returns through the other pair. In a four high and more complex mill only two of the rolls are working rolls, the other backing or supporting rolls minimize flexing of the working rolls. A *Universal Mill* has multiple rolls position to work both the vertical and horizontal axes of the material. Rolls are carried in *Stands* and material usually passes through a number of stands during a rolling cycle. In a *Tandem Mill*, two or more parallel stands are grouped close together so that the material enters the second and subsequent rolls before clearing the first. In a *Looping Mill*, two or more stands live side by side so that material, usually bar, emerging from one is directed in a loop to enter the second stand. In a *Cross Country Mill*, the material completely clears each stand before traveling to the next.

Rolling Mills

Machines used to decrease the cross-sectional area of metal stock and to produce certain desired shapes as the metal passes between rotating rolls mounted in a framework comprising a basic unit called a *stand*. Cylindrical rolls produce flat shapes; grooved rolls produce rounds, squares, and structural shapes. See also *four-high mill*, *Senzimir mill*, and *two-high mill*.

Rolling Texture

Preferred orientation produced by rolling.

Rolling Velocity

See *sweep velocity*.

Rolling-Contact Fatigue

Repeated stressing of a solid surface due to rolling contact between it and another solid surface or surfaces. Continued rolling-contact fatigue of bearing or gear surfaces may result in rolling-contact damage in the form of subsurface fatigue cracks and/or material pitting and spallation.

Rolling-Contact Wear

Wear to a solid surface that results from rolling contact between that surface and another solid surface or surfaces.

Röntgen

The unit of radiation dose, $1R + 2.58 \times 10^{-4} \text{ C/kg}$.

Room Temperature

A temperature in the range of -20°C to 30°C (-68°F to 85°F). The term room temperature is usually applied to an atmosphere of unspecified relative humidity.

Room-Temperature Setting Adhesive

An adhesive that sets (to handling strength) within an hour at temperatures from 20°C to 30°C (-68°F to 85°F) and later reaches full strength without heating. Compare with *cold-setting adhesive*, *hot-setting adhesive*, and *intermediate temperature setting adhesive*.

Room-Temperature Vulcanizing (RTV)

Vulcanization or curing at room temperature by chemical reaction, particularly of silicones and other rubbers.

Root

See preferred term *root of joint* and *root of weld*.

Root Concavity

A hollow in the root of a weld.

Root Crack

A crack in either the weld or heat-affected zone at the root of a weld. See the term *weld crack*.

Root Edge

A *root face* of zero width.

Root Face

The portion of a weld groove face adjacent to the root of the joint.

Root Gap

See preferred term *root opening*.

Root Head

A weld deposit that extends into or includes part or all of the root of the joint. See also *root of joint*.

Root Mean Square (rms)

(1) The square root of the arithmetic mean of the squares of the numbers in a given set of numbers. (2) The effective value of an

alternating periodic voltage or current. (3) A term describing the surface roughness of a machined surface. (4) The area beneath a waveform. See also *surface roughness*.

Root of Joint

The portion of a weld joint where the members are closest to each other before welding. In cross section, this may be a point, a line, or an area. Same as *root of weld preparation*.

Root of Weld

(1) In the case of a weld to be made; it is the area of the parent materials where the first deposit is to be made. In the case of a completed weld, it is the face of the first weld run that is remote from the operator. (2) The points, at which the weld bead intersects the base-metal surfaces either nearest to or coincident with the *root of joint*.

Root of Weld Preparation

The area where two surfaces to be joined are in the closest approach in which the first run will be deposited.

Root Opening

In a weldment, the separation between the members at the *root of joint* prior to welding.

Root Pass

The first bead of a *multi-pass weld*, laid in the *root of joint*.

Root Penetration

The depth that a weld extends into the *root of joint*, measured on the centerline of the root cross section. See the term *joint penetration*.

Root Radius

See preferred term *groove radius*.

Root Rolling

The rolling of cut thread roots and similar features to induce favorable residual stresses to resist fatigue.

Root Run/Pass (of Weld)

The first run of a multiple run weld.

Rooting

See *oxide rooting*.

Root-Mean-Square End-to-End Distance

A measure of the average size of a coiled polymer molecule, usually determined by light scattering.

R

Rosebuds

Concentric rings of distorted coating, giving the effect of an opened rosebud. Noted only on *minimized spangle*.

Rosette

(1) Rounded configuration of microconstituents in metals arranged in whorls or radiating from a center. (2) Strain gages arranged to indicate at a single position strains in three different directions. (3) Typically, three gages are aligned at 120° to each other. See also *strain gage*.

Rosette (Star)Fracture

A tensile fracture that exhibits a central fibrous zone, and intermediate region of radial shear, and an outer circumferential shear-lip zone. Rosette fractures are often observed in temper-embrittled steels. See also *shear lip* and *temper embrittlement*.

Rosette Graphite

Arrangement of graphite flakes in which the flakes extend radially from the center of crystallized areas and gray cast iron. See the term *flake graphite*.

Rosin

The common resin of several varieties of pine tree, found widely distributed in North America and Europe. It is obtained by cutting a longitudinal slice in the tree and allowing the exudation to drip into containers. The liquid resin is then distilled to remove the turpentine, and the residue forms what is known as *gum rosin*, or *pine gum*. *Wood rosin* is obtained by distillation of old pine stumps. It is darker than gum rosin and is inferior for general use.

Rosin contains seven acids with very similar characteristics but consists chiefly of *abietic acid*. Normally, when gum rosin is heated, the natural pimaric acid isomerizes to form abietic acid; but in the production of turpentine and rosin from pine sap, the turpentine is removed by steam distillation, and various acids are then extracted. Pimaric acid is closely related to abietic acid. It reacts with maleic and anhydride, and *maleopimaric acid* is used in printing inks and coatings. Rosin has a specific gravity of about 1.08 and a melting point of about 180°F (82°C), and it is soluble in alcohol, turpentine, and alkalis. It is used in varnishes, paint driers, soluble oils, paper sizing, and belt dressings; and for compounding with rubber and other resins; and for producing many chemicals.

Rosin is generally graded commercially by letters according to color. The darkest grade is B, and the highest is W. Extra grades are A, nearly black, and WW, water-white. Thirteen color grades are designated under the Naval Stores Act. The dark grades of wood rosin are considered inferior. They have a high melting point and low acid number and are used for making rosin oil; for battery waxes, thermoplastics, and dark varnish; and for linoleum manufacture. Rosin is usually marketed in barrels of 280 lb (127 kg). **Naval stores** is an old name for rosin and turpentine. Palletized rosin consists of free-flowing, dustless pellets produced by coating droplets of molten rosin with inert powder.

Hardened rosin is a weak resonant made by adding 6%–8% high-calcium lime to melted rosin. It is used in some varnishes.

Hydrogenated rosin has greater resistance to oxidation than common rosin, has less odor and taste, and has a pale color that is

more stable to light. It is used in protective coatings, in paper size, in adhesives, in soaps, and as a tackifier and plasticizer in rubber. Because of its saturated nature, it cannot be used for rosin-modified plastics.

Rosin is hardened by polymerization to form a dipolymer of abietic acid. The product is then pale in color and has a lower acid number and a higher melting point than rosin. *Poly-pale resin*, of Hercules, is a polymerized rosin with a melting point of 208°F–217°F (98°C–103°C), acid number 152–156, and saponification value 157–160. It can be substituted for natural copals in paints, and in gloss oil, it gives water resistance and high viscosity. In the making of metallic resins, it gives higher melting points, higher viscosity, and better solubility than natural rosin. Compare with *resin*.

Rosin Flux

A soldering flux having a rosin base that becomes interactive after being subjected to the soldering temperature. See also *flux*.

Rotary Filling and Burring

Machining or smoothing surfaces with contour-fitting rotary tools where only a minimum amount of material is to be removed.

Rotary Forging

A process in which the workpiece is pressed between a flat anvil and a swiveling (rocking) die with a conical working face; the platens move toward each other during forging. Also called orbital forging. Compare with *radial forging*. See *Pilger mill* and *tube making*.

Rotary Furnace

A circular furnace constructed so that the hearth and workpieces rotate around the axis of the furnace during heating. The charge is inserted at one point and remains in the hearth for nearly a full circle before being withdrawn. Also called rotary hearth furnace.

Rotary Press

A machine for forming powder metallurgy parts that is fitted with a rotating table carrying multiple die assemblies in which powder is compacted.

Rotary Retort Furnace

A continuous-type furnace in which the work advances by means of an internal spiral, which gives good control of the retention time within the heated chamber.

Rotary Roughening

A method of surface roughening prior to thermal spraying wherein a revolving roughening tool is pressed against the surface being prepared, while either the work, or the tool, or both, move.

Rotary Seal

A mechanical seal that rotates with a shaft and is used with a stationary mating ring.

Rotary Shear

(1) A sheet metal cutting machine with two rotating-disk cutters mounted on parallel shafts driven in unison. (2) A device for cutting sheet and plate utilizing a pair of driven, overlapping disk cutters.

Rotary Swager

A swaging machine consisting of a power-driven ring that revolves at high speed, causing rollers to engage cam surfaces and force the dies to deliver hammer-like blows on the work at high frequency. Both straight and tapered sections can be produced.

Rotary Swaging

A *bulk forming* process for reducing the cross-sectional area or otherwise changing the shape of bars, tubes, or wires by repeated radial blows with one or more pairs of opposed dies.

Rotating Bending Fatigue Test

Various fatigue tests in which a cylindrical test piece is rotated while under a lateral load so that any point on its periphery undergoes one complete tensile/compression reverse cycle per revolution. The test piece may be supported as a cantilever, or in three-point or four-point bending depending on the particular machine.

Rotating Electrode Powder

An atomized powder consisting exclusively of solid spherical or near-spherical particles.

Rotating Electrode Process

A method for producing metal powders wherein a consumable metal or alloy electrode is rotated during arc melting at very high speeds, and the molten droplets are propelled by centrifugal force toward the wall of a large collecting chamber while solidifying in flight. If the consumable electrode is melted by an electric arc, the process is called the rotating electrode process, or REP; if it is melted by a plasma arc, the process is called the plasma rotating electrode process, or PREP; and if the bar is melted by a laser, the process is called the laser rotating electrode process (LREP). It is also possible to use electron beam melting. The melting technique used depends primarily on the need for cleanliness of the powder and on the type of atmosphere required for the alloy.

Rotational Casting

A method used to make hollow articles from thermoplastic materials. The material is charged into a hollow mold capable of being rotated in one or two planes. The hot mold fuses the material into a gel after the rotation has caused it to cover all surfaces. The mold is then chilled, and the product is stripped out.

Rotational Molding

The preferred term for a variation of the *rotational casting* process that uses dry, finely divided (35 mesh, or 500 μ) plastic powders, such as polyethylene, rather than fluid materials. After the powders are heated, they are fused against the mold walls forming a hollow item with uniform wall thickness.

Rouge

A hydrated iron oxide used for polishing metals and in break-in lubricants for aluminum bronze bearings. It has a Mohs hardness of 5.5–6.5 and is made by calcining ferrous sulfate and driving off the sulfur. The color is varying shades of red; the darker the color, the harder the rouge. The grains are rounded, unlike the grains of crocus. The pale-red rouge is used for finishing operations; the other grades are used for various polishing of metal surfaces. *Stick rouge* is made of finely crushed powder. Although the word rouge means red, materials of other colors are used for buffing and are called rouge. *Black rouge*, also called *Glassite*, is magnetic iron oxide made by precipitating ferrous sulfate with caustic soda. It is used for buffing but is not popular because it stains the skin. *Green chrome rouge* is *chromium oxide*, CrO₃, made by the strong heating of chromic hydroxide. It is used for buffing stainless steels. When used as a paint pigment, it is called *Guignet's green*. *Satin rouge* is a name applied to lamp black when used as a polishing medium in the form of brick for polishing silverware. **Crocus** is a name applied to metal powders of the deep-yellow, brown, or red color made into cakes with grease for polishing. *Polishing crocus* is usually red ferric oxide used for a buffing glass and jewelry. Crocus cloth is a fabric coated with red iron oxide, marketed in sheets and used for polishing metals.

Rouge Finish

A highly reflective finish produced with rouge (finely divided, hydrated iron oxide) or other very fine abrasive, similar in appearance to the bright polish or mirror finish on sterling silver utensils.

Rough Blank

A *blank* for a metal forming or drawing operation, usually of a regular outline, with necessary stock allowance for process metal, which is trimmed after forming or drawing to the desired size.

Rough Grinding

Grinding without regard to finish, usually to be followed by a subsequent operation.

Roughing Stand

The first stand (or several stands) of rolls through which a reheated *billet* passes in front of the finishing stands. See also *rolling mills* and *stand*.

Rough Machining

(1) Machining without regard to finish, usually to be followed by a subsequent operation. (2) Machining to an approximate size, usually oversize so that subsequent final or finish machining achieves the required dimension and finish.

Roughness

(1) Relatively finely spaced surface irregularities, the heights, widths, and directions of which establish the predominant surface pattern. (2) The microscopic peak-to-valley distances of surface protuberances and depressions. See also *surface roughness* and *surface finish*.

R

Roughness-Width Cutoff

The maximum width of surface irregularities to be included in the measurement of roughness height.

Rough-Polishing Process

A polishing process having the primary objective of removing the layer of significant damage produced during earlier machining and abrasion stages of a medley graphic preparation sequence. A secondary objective is to produce a finish of such quality that a final polish can be produced easily.

Rough Threading

A method of surface roughening prior to thermal spraying, which consists of cutting threads with the sides and tops of the threads jagged and torn.

Routing

Cutting out and contouring edges of various shapes in a relatively thin material using a small diameter rotating cutter, which is operated at fairly high speeds.

Roving

A number of yarns, strands, tows, or ends collected into a parallel bundle with little or no twist. Rovings are used to produce fiber-reinforced plastics. See also *woven roving*.

Roving Cloth

A textile fabric, coarse in nature and woven from roving, used in reinforced plastics.

Row Nucleation

The mechanism by which stress-induced crystallization is initiated in reinforcing fibers for composites, usually during fiber spinning or hot drawing.

RRIM

See *reinforced reaction injection molding*.

RSJ

Rolled steel joist.

RTM

See *resin transfer molding*.

RTV

See *room-temperature vulcanizing*.

Rub Mark

See *abrasion*.

Rubber

This term originally referred to a natural or tree rubber, which is a hydrocarbon polymer of isoprene units. With the development of synthetic rubbers having some rubbery characteristics but differing in chemical structure as well as properties, a more general designation was needed to cover both natural and synthetic rubbers. The term *elastomer*, a contraction of the words elastic and polymer, was introduced and defined as a substance that can be stretched at room temperature to at least twice its original length and, after having been stretched and the stress removed, returns with force to approximately its original length in a short time.

Three requirements must be met for rubbery properties to be present in both natural and synthetic rubbers: long threadlike molecules, flexibility in the molecular chain to allow flexing and coiling, and some mechanical or chemical bonds between molecules.

A useful way of visualizing rubber structure is to consider as a model a bundle of wiggling snakes in constant motion. When the bundle is stretched and released, it tends to return to its original condition. If there were no entanglements, stretching the bundle would pull it apart. The more entanglements, the greater the tendency to recover, corresponding to cross-links in rubber. In rubbers, the characteristic property of reversible extensibility results from the randomly coil arrangement of the long polymer chains. Upon extension, the chains are elongated in a more or less orderly array. The tendency to revert to the original coiled disarray upon removal of the stress accounts for the elastic behavior. Vulcanizing rubber increases the number of cross-links and improves the properties.

Natural rubber and most synthetic rubbers are also commercially available in the form of latex, a colloidal suspension of polymers in an aqueous medium. Natural rubber comes from trees in this form and many synthetic rubbers are polymerized in this form; some other solid polymers can be dispersed in water.

Latexes are the basis for a technology and production methods completely different from the conventional methods used with solid rubbers.

Processing

In the crude state, natural and synthetic rubbers possess certain physical properties that must be modified to obtain useful end products. The raw or unmodified forms are weak and adhesive. They lose their elasticity with use, change markedly in physical properties with temperature, and are degraded by air and sunlight. Consequently, it is necessary to transform the crude rubbers by compounding and vulcanization procedures into products that can better fulfill a specific function.

Curatives and Vulcanization

After the addition of curing or vulcanizing agents to rubber, the application of heat causes cross-linking, yielding a durable product by binding the long chains together. Sulfur, the first successful curing ingredient, is the basis of vulcanization. However, various chemicals or combinations of chemicals are also capable of vulcanizing rubber. These include oxidizing agents, such as selenium or tellurium, organic peroxides, and nitro compounds, and also generators of free radicals, such as organic peroxides, azo compounds, and certain organic sulfur compounds such as the alkyl disulfides.

Sulfur alone results in very slow cure rates and develops less than optimum physical properties in the rubber. Several classes of compounds have been found that accelerate the rate of vulcanization, improve the efficiency of the vulcanization reaction, and reduce the

sulfur requirements, in general enhancing the physical properties of the vulcanized rubber.

Accelerators are substances that act as catalysts in the vulcanization process, initiating free radicals. The first accelerators to be used in the rubber industry were inorganic chemicals, such as the basic carbonates and oxides of lead supplemented by magnesium or lime.

Some rubbers can be vulcanized by gamma radiation.

Pigments

Vulcanization improves the elasticity and aging properties of rubber, but in most cases it is necessary to enhance further such properties as tensile strength, abrasion resistance, and tear resistance by incorporation of fillers. Those that improve specific physical properties are known as reinforcing fillers; those that serve primarily as diluents are classed as inert fillers. The physical properties of the resulting vulcanization are affected by both the type and amount of filler.

The most universally used reinforcing filler in the rubber industry is carbon black. The types used commercially in the greatest bulk for this purpose include furnace and thermal blacks.

In addition to the carbon blacks, inorganic reinforcing agents, such as zinc oxide and the silicas, are used for reinforcement of light-colored end products.

Specific Types of Rubber

One rubber is obtained from natural sources in commercial quantities. In addition, a number of synthetic compounds are classified as rubbers.

Smoked sheet and pale crepe represent the forms in which the major portion of natural rubber is commercially available.

Natural Rubber (NR)

Although natural rubber may be obtained from hundreds of different plant species, the most important source is the rubber tree. Natural rubber is *cis*-1,4-polyisoprene, containing approximately 5000 isoprene units in the average polymer chain.

The economic competition from synthetic rubbers has stimulated research and development in natural rubber by increasing productivity in the field, improving uniformity and quality of the product and packaging, and developing modified natural rubbers with specific properties.

Increased productivity has been achieved by increasing the yield of the trees by cross-pollination of high-rubber-yielding clones, use of chemical stimulants, and better tapping and collection methods. These methods have resulted in large increases in yields on Malaysian estates, with much greater increases anticipated.

With improved productivity and better processing methods and controls, much better quality and uniformity have been achieved. This made possible the development of standard Malaysian rubbers (SMR) to meet specifications on a number of properties, including dirt and ash content, viscosity, and copper and manganese content.

In addition, experimental work has been done on improved collection of latex by microtapping and collecting in polyethylene bags, and trees having three parts: a high-yielding trunk system grafted onto a strong root system and an improved, more prolific leaf system grafted onto the trunk.

Despite competition from synthetic rubbers and a great reduction in percentage use worldwide of natural rubber, the tonnage of natural rubber continues a steady growth in parallel with the growth of the industry.

Styrene-Butadiene Rubbers (SBR)

The extensive development of the synthetic rubber industry originated with the World War II emergency, but continued expansion has been the result of the superiority of the various synthetic rubbers in certain properties and applications. The most important synthetic rubbers and the most widely used rubbers in the entire world are the styrene-butadiene rubbers (SBR).

Formally designated GR-S, SBRs are obtained by the emulsion polymerization of butadiene and styrene in varying ratios.

When SBR is used in light-duty tires, such as passenger car tires, the cold-rubber compounds have proved equal or superior to natural rubber treads. However, they are inferior to natural rubber for truck tires because of the greater heat buildup during flexing. The cold, oil-extended type, prepared by the replacement of a portion of the polymer by a heavy-traction oil, accounts for more than 50% of the cold-rubber production. Its advantage is primarily economic. Master batches, containing both oil and carbon black, have the advantage of process simplification.

In general, the compounding and processing methods for all the SBR types are similar to those of natural rubber. Although natural rubber is superior with respect to lower heat buildup, resilience, and hot tear strength, the SBR types are more resistant to abrasion and weathering. However, carbon black or some other reinforcing fillers must be added to the SBR to develop the best physical properties. Unlike natural rubber, SBR does not crystallize on stretching and thus has low tensile strength unless reinforced. The major use for SBR is in tires and tire products. Other uses include belting, hose, wire and cable coatings, flooring, shoe products, sponge, insulation, and molded goods.

cis-1,4-Polybutadiene (BR)

Work on the duplication of natural rubber stimulated interest in stereoregulated polymerization of butane, particularly of the high *cis*-1,4 structure.

Black-loaded vulcanizates of *cis*-1,4-polybutadiene rubbers exhibit good physical properties, such as lower heat generation, higher resilience, improved low-temperature properties, and greatly improved abrasion resistance. Processing properties are rather poor but can be greatly improved by employing blends with natural rubber or SBR. Tests on retreaded passenger tires gave outstanding abrasion resistance and increased resistance to cracking as compared with natural rubber. In passenger tires, *cis*-1,4-polybutadiene improves tread wear by about 1% for each percent of polybutadiene and the tread compound. In truck tires, a blend with natural rubber gives 14% more wear than natural rubber alone.

Butyl Rubber

Isobutylene and isoprene or butadiene obtained from cracked refinery gases are the primary raw materials required for the manufacture of butyl rubber.

Neither neoprene nor butyl rubber requires carbon black to increase its tensile strength, but the reinforcement of butyl rubber by carbon black or other fillers does improve the modulus and increases their resistance to tear and abrasion.

The excellent resistance of butyl rubbers to oxygen, ozone, and weathering can be attributed to the smaller amount of unsaturation present in the polymer molecule. In addition, these rubbers exhibit good electrical properties and high permeability to gases. The high permeability to gases results in use of butyl as an inner liner in tubeless tires. Other widespread uses are for wire and cable products, injection-molded and extruded products, hose, gaskets, and sealants, and where good damping characteristics are needed.

R

Ethylene–Propylene Polymers (EPM, EPDM)

Stereospecific catalysts are employed to make synthetic rubbers by the copolymerization of ethylene and propylene. Either monomer alone polymerizes to a hard, crystallizable plastic, but copolymers containing 35%–65% of either monomer are amorphous, rubbery solids. Special catalysts must be employed because ethylene polymerizes many times faster than propylene. The best results seem to be obtained with complex catalysts derived from an aluminum alkyl and a vanadium chloride or oxychloride.

Processing techniques and factory equipment used with other rubbers can also be applied to these copolymers. The mechanical properties of their vulcanizates are generally approximately equivalent to those of SBR.

Terpolymers containing ethylene, propylene, and a third monomer, such as dicyclopentadiene, have become more popular because they contain unsaturation and thus may be sulfur-cured by using more or less conventional curing systems.

Neoprene (CR)

One of the first synthetic rubbers used commercially in the rubber industry, neoprene is a polymer of chloroprene, 2-chloro butadiene-1,3. In the manufacturing process, acetylene, the basic raw material, is dimerized to vinyl-acetone and then hydrochlorinated to the chloroprene monomer.

Sulfur is used to vulcanize some types of neoprene, but most of the neoprenes are vulcanized by the addition of basic oxides such as magnesium oxide and zinc oxide. The cure proceeds through reaction of the metal oxide with the tertiary allylic chlorine that arises from the small amount of 1,2-polymerization that occurs. Other compounding and processing techniques follow similar procedures and use the same equipment as for natural rubber. One of the outstanding characteristics of neoprene is the good tensile strength without the addition of carbon black filler. However, carbon black and other fillers can be used when reinforcement is required for specific end-use applications that require increased tear and abrasion resistance.

The neoprenes have exceptional resistance to weather, sun, ozone, and abrasion. They are good in resilience, gas impermeability, and resistance to heat, oil, and flame. They are fairly good at low temperature and electrical properties. This versatility makes them useful in many applications requiring oil, weather, abrasion, or electrical resistance or combinations of these properties, such as wire and cable, hose, belts, molded and extruded goods, soles and heels, and adhesives.

Nitrile Rubber (NBR)

Much of the basic pioneering research on emulsion polymerization systems was with nitrile-type rubbers. These rubbers, first commercialized as the German Buna N types in 1930, are copolymers of acrylonitrile and a diene, usually butadiene.

Both sulfur and nonsulfur vulcanizing agents may be used to cure these rubbers. Carbon black or other reinforcing agents are necessary to obtain the optimum properties. If proper processing methods are followed, the nitrile rubbers can be blended with natural rubber, polysulfide rubbers, and various resins to provide characteristic such as increased tensile strength, better solvent resistance, and improved weathering resistance.

The nitrile rubbers have outstanding oil, grease, and solvent resistance. Consequently, the commercial usage of these rubbers is largely for items in which these properties are essential. Another major usage is the utilization of the latex form for adhesives and for the finishing of leather, impregnation of paper, and the manufacture of nonwoven fabrics.

cis-1,4-Polyisoprene (IR)

In 1954, synthetic *cis*-1,4-polyisoprene was made from isoprene with two different classes of catalysts. The first class includes lithium and the lithium alkyls. The second class uses a mixture of an aluminum alkyl and titanium tetrachloride, the system first used for the low-pressure polymerization of ethylene. Both catalyst system polymerizations are carried out in hydrocarbon solution and require highly purified monomer and solvent. Traces of air, moisture, and most polar compounds adversely affect reaction rates, polymer properties, and structure.

The *cis*-1,4 polymer structure obtained with these catalysts is also characteristic of natural *Hevea* rubber. The presence of a high *cis* content appears necessary for the desirable physical properties with *Hevea* in contrast to the inferior properties of emulsion-type polyisoprene, which contains mixed *cis*-, *trans*-1,2-, and 3,4-isoprene units.

This polymer and the corresponding butadiene polymer discussed above are called stereorubbers because of their preparation with stereospecific catalysts. The emulsion polymers are formed by a free-radical mechanism that does not permit control of the molecular structure. Stereorubbers are formed by anionic mechanisms that permit nearly complete control of the structure of the growing polymer chain in stereoregular fashion.

The type of catalyst employed influences the structure of the polymer. The aluminum–titanium-catalyzed rubbers exhibit, on stretching, a gradual crystallization somewhat slower than natural, and they are readily processed because the molecular weight range tends to be less than that of natural rubber. The lithium-catalyzed rubbers contain about 93% *cis*-1,4 structure; they exhibit very little tendency to crystallize and cannot be processed satisfactorily until they have undergone substantial mastication to reduce their very high molecular weight values to a level more nearly resembling that of well masticated natural rubber.

The differences in structure influence the properties of these rubbers. The alumina–titanium-catalyzed rubber, because it crystallizes more readily, exhibits better hot tensile strength. The lithium-catalyzed polymer, as it is of higher molecular weight exhibits higher resilience and less heat generation. Both types, when compounded and cured, produce physical properties that closely approach, or are equivalent to, natural rubber.

The tests with heavy-duty tires for trucks, buses, and airplanes have shown that with respect to wear and heat buildup the isoprene rubbers are comparable to natural rubber during tire operation. Polyisoprene rubber has passed qualification tests in high-speed jet aircraft tires to withstand landing speeds as high as 250 mi/h (112 m/s).

Other Rubbers

There are other specialty rubbers available that are important because of specific properties, but in the aggregate, they make up only approximately 2% of the world production of synthetic rubbers.

Silicone Rubbers

Silicone rubber is a linear condensation polymer based on dimethyl siloxane. In the preparation, dimethyl dichlorosilane is hydrolyzed to form dimethyl silanol, which is then condensed to dimethyl siloxane, and this, upon further condensation, yields dimethyl polysiloxane, the standard silicone rubber.

Various types of silicone rubbers are produced by substituting some of the methyl groups in the polymer with other groups such as phenol or vinyl. Advantages of this type of substitution are

evidenced by improvements in specific properties. For example, the presence of phenol groups in the polymer chain gives further improvement in low-temperature properties. Fluorine-containing side groups improved chemical resistance. Many types are commercially available, ranging from fluid liquids to tough solids.

Because sulfur is not effective for the vulcanization of most silicone rubbers, a strong oxidizing agent, such as benzoyl peroxide, is used; the cross-linking produced is random.

Although the standard silicone rubbers are not reinforced by carbon black, the physical properties can be improved by the incorporation of various inorganic fillers such as titania, zinc oxide, and silica, which act as reinforcing and modifying agents. The physical, chemical, and electrical properties can be altered by varying the type and amount of these fillers. Carbon black can be used as a filler with vinyl-containing polymers.

In general, the silicone rubbers have relatively poor physical properties and are difficult to process. However, they are the most stable of rubbers that are capable of remaining flexible over a temperature range of -90°C to 316°C . They are unaffected by ozone, are resistant to hot oils, and have excellent electrical properties. Their most extensive uses are for wire and cable insulation, tubing, packings, and gaskets in aerospace and aircraft applications. In the form of dispersions and pastes, they are used for dip-coating, spraying, brushing, and spreading. Silicone rubbers are important in medical and surgical devices because of their property, unique among elastomers, of being compatible with body tissues. Fast, automatic, economical injection molding of liquid silicones has been developed.

Hypalon

Hypalon is the DuPont trade name for a family of chlorosulfonated polyethylenes prepared by treating polyethylenes with a mixture of chlorine and sulfur dioxide, whereby a few scattered chlorine and sulfonyl chloride groups are introduced into the polyethylene chain. By this treatment, polyethylene is converted to a rubberlike material in which the undesirable degree of crystallinity is destroyed but other desirable properties of polyethylene are retained. The outstanding chemical stability of Hypalon results from the complete absence of unsaturation in the polymer chain.

Vulcanization is accomplished by means of metallic oxides, such as litharge, magnesia, or red lead, and the presence of an accelerator as a stock in itself. Hypalon can be blended with other types of rubbers to provide a wide range of properties.

Hypalon has extreme resistance to ozone. Its chemical resistance to strong chemicals, such as nitric acid, hydrogen peroxide, and strong bleaching agents, is superior to any of the commonly used rubbers. These vulcanizates also have good heat resistance, mechanical properties, and unlimited color ability. Typical applications include white sidewall tires and a variety of sealing, waterproofing, insulating, and molded items.

Epichlorohydrin Elastomers

These elastomers are polymers of epichlorohydrin. The two main types of epichlorohydrin elastomers are the homopolymer (CO) and the copolymer (ECO) of epichlorohydrin and ethylene oxide. The copolymer has a lower brittle point, better resilience, and a lower specific gravity than the homopolymer but is not as good in high-temperature properties.

Since the backbone of the molecule is saturated, these elastomers cannot be vulcanized with sulfur. Cross-linking is achieved by reaction of the chloromethyl side group with diamines of thioureas. A metal oxide is also required.

They exhibit outstanding ease of processing; extreme impermeability to gases; moderate tensile strength and elongation; high modulus; good abrasion resistance; good heat aging; excellent resistance to hot oil, water, perchloroethylene, acids, bases, and ozone; good low-temperature properties; and electrical properties ranging between those of a poor insulator and a good conductor, depending on compounding.

These properties make the epichlorohydrin elastomers useful in gaskets for oil field specialties, diaphragms, and pump and valve parts; hose for low-temperature flexibility; oil and fuel resistance, or gas impermeability applications, and mechanical goods such as belting, wire, and cable.

Thermoplastic Elastomers

Proper choice of catalyst and order of procedure in polymerization have led to development of thermoplastic elastomers. The leading commercial types are styrene block copolymers with a structure that, unlike the random distribution of monomer units in conventional polymers, consists of polystyrene segments or blocks connected by rubbery polymers such as polybutadiene, polyisoprene, or ethylene-butylene polymer. These types can be designated SBS, SIS, and SEBS, respectively. Other types of thermoplastic elastomers, such as the polyester type, have also been developed.

SBS, SIS, and SEBS polymers, when heated to a temperature above the softening point of the styrene blocks, can be processed and shaped like thermoplastics but, when cooled, act like vulcanized rubber, with the styrene block serving as cross-links. Thus, it is unnecessary to vulcanize. Also, scrap or excess material can be reused.

Thermoplastic elastomers are very useful in providing a fast and economical method of producing a variety of products; including molded goods, toys, sporting goods, and footwear. One of the disadvantages for many applications is the low softening point of the thermoplastic elastomers. Attempts to modify the composition and structure to raise the softening temperature have generally resulted in inferior rubbery properties.

Fluoroelastomers

These are basically copolymers of vinylidene fluoride and hexafluoropropylene.

Because of their fluorine content, they are the most chemically resistant of the elastomers and also have good properties under extremes of temperature conditions. They are useful in the aircraft, automotive, and industrial areas.

Polyurethane Elastomers

Polyurethane elastomers are of interest because of their versatility and variety of properties and uses. They can be used as liquids or solids in a number of manufacturing methods. The largest use has been for making foam for upholstery and bedding, but difficulties have been encountered in public transportation due to flammability.

Polysulfide Rubbers

These rubbers have a large amount of sulfur in the main polymer chain and are therefore very chemically resistant, particularly to oils and solvents. They are used in such applications as putties, caulks, and hose for paint spray, gasoline, and fuel.

Polyacrylate Rubbers

Polyacrylate rubbers are useful because of their resistance to oils at high temperatures, including sulfur-bearing extreme-pressure lubricants.

R

Products

A wide variety of products have a rubber, or elastomer, as an essential component. Most rubber products contain a significant amount of nonrubber materials, used to impart processing, performance, or cost advantages.

The automotive industry is the biggest consumer of rubber products. About 60% of all rubber used goes into the production of passenger, bus, truck, and off-the-road tires. In addition, a typical automobile contains about 68 kg of rubber products such as belts, hoses, and cushions. Outside the automotive area, a wide variety of rubber products are produced, including such familiar items as rubber bands, gloves, and shoe soles.

The formulation and manufacture of rubber products are as diverse as the wide variety of applications for which they are intended. This discussion is limited to the more common methods of manufacture and those that apply to the widest variety of products. In general, the manufacture of rubber products involves compounding, mixing, processing, building or assembly, and vulcanization.

Compounding

The technical process of determining what the formulation components of a rubber product should be is called compounding. This term is also applied to the actual process of weighing out the individual components in preparing for mixing.

Rubber is the backbone of any rubber product. Natural rubber, obtained from the latex of rubber trees, accounts for about 23% of all rubber consumed in the United States. The balance is synthetic rubber. Of the synthetic rubbers, SBR (styrene-butadiene rubber) and polybutadiene rubber are most important, accounting for 71% of synthetic rubber production. A variety of specialty synthetic rubbers, such as butyl, EPDM, polychloroprene, nitrile, and silicone, account for the balance of synthetic rubber production.

Choice of the rubber to be used depends on cost and performance requirements. The specialty rubbers often give superior performance properties but do so at higher product cost.

Many rubber products contain less than 50% by weight of rubber. The balance is a selection of fillers, extenders, and processing or protective coatings.

In products other than tires, clays may be added as extenders, silicas as reinforcing agents, and plasticizers for flex or fire-retardant properties; colors or brightening agents may also be used.

Mixing

This step accomplishes an intimate and homogeneous mix of the formulation components. Most large-volume stocks are mixed in internal mixers; these operate with two winged rotors with the compounding gradients forced into the rotors by an external ram.

There are thousands of different recipes, each designed for different purposes and each requiring a mixing procedure of its own. In addition, various manufacturers differ in their ideas as to precisely how the mixing operation should be conducted, and the equipment in various plants differs widely. The trend is toward more automation in this process, both in weighing and changing the ingredients into the mixer and in handling the stock after discharge.

Forming

Usually, forming operations involve either extrusion into the desired shape or calendaring to sheet the material to some specified gauge or to apply a sheet of the material to a fabric.

Building

Building operations, varying from simple to complex, are required for products such as tires, shoes, fuel cells, press rolls, conveyor belts, and life rafts. These products may be built by combining stocks of different compositions or by combining rubber stocks with other construction materials such as textile cords, woven fabric, or metal. For a few products, no building operations are required. For example, many molded products are made by extruding the rubber, cutting it into lengths, and placing it in the mold cavities. Also, extruded products that are given their final shape by the die used in the extruder are ready for the final step of vulcanization, with no intermediate building operations.

The building operations for tires vary widely, depending on the kind of tire to be built at the equipment available in the particular plant. For example, the cord reinforcement may be of polyester, nylon, or steel wire; the number of plies required increases as the size and service requirements increase; the trip proper may be of a different composition than the tread base and side walls; one of the side walls may be made of a white stock; the construction may be of the tubeless variety, in which case an air-barrier ply of rubber is applied to the inside surface of the first ply; a puncture-sealing layer may be applied to the inside surface; or there may be several bead assemblies instead of only one.

Increasing popularity of radial tires has caused some basic changes in tire manufacturing operations. In a radial tire, the reinforcement cords in the body, or carcass, of the tire are placed in a radial direction from bead to bead. Radial tires require special building drums and result in a green tire of a different appearance from the barrel-shaped green bias-ply tire.

Vulcanization

The final process, vulcanization, follows the building operation or, if no building operations are involved, the forming operation.

Vulcanization is the process that converts the essentially plastic, raw rubber mixture to an elastic state. It is normally accomplished by applying heat for a specified time at the desired level. The most common methods for vulcanization are carried out in molds held closed by hydraulic presses and heated by contact with steam-heating platens, which are a part of the press in open steam in an autoclave; under water maintained at a pressure higher than that of saturated steam at the desired temperature; in air chambers in which hot air is circulated over the product; or by various combinations of these methods.

The vast majority of products are sulfur-cured; that is, sulfur cross-links join the rubber chains together. For special applications, vulcanization may take place without the use of sulfur, for example, in the resin- or peroxide-initiated cross-links or metal-oxide-cured polychloroprene.

The time and temperature required for vulcanization of a particular product may be varied over a wide range by proper selection of the vulcanizing system. The usual practice is to use as fast a system as can be tolerated by the processing steps through which the material will pass without "scorching," that is, without premature vulcanization caused by heat during these processing steps. Rapid vulcanization affects economies by producing the largest volume of goods possible from the available equipment. This is particularly the case for products made in molds, because molds are costly, and their output is determined by the number of heats that can be made per day.

The rate of vulcanization increases exponentially with an increase in temperature; hence, the tendency is to vulcanize at the highest temperature possible. In practice, this is limited by many factors, and the practical curing temperature range is 127°C–171°C.

There are numerous exceptions both below and above this range, but it probably covers 95% of the products made.

Finishing operations following vulcanization include removal of mold flash, sometimes cutting or punching to size, cleaning, inspection for defects, addition of fittings such as valves or couplings, painting or varnishing, and packing.

Latex Technology

In addition to the technology of solid rubber, there is a completely different, relatively small but important part of the rubber industry involving the manufacture of products directly from natural rubber latex from the tree, synthetic latex from emulsion polymerization, or aqueous dispersions made from solid rubbers.

In latex technology, materials to be added to the rubber are colloiddally dispersed in water and mixed into the latex, a process involving the use of lighter equipment and less power than the mixing of solid rubber compounds. The latex compound can then be used in a variety of processes such as coating or impregnating of cords, fabrics, or paper; in paints or adhesives; molding (such as in toys); dipping (for thin articles like balloons, or household and surgeon's gloves); rubber thread (for garments); and production of foam. Latex technology is particularly important in producing articles for medical and surgical uses.

Rubber Blanket

A sheet of rubber or other resilient material used as an auxiliary tool in forming.

Rubber Forming

Forming a sheet metal wherein rubber or another resilient material is used as a functional die part. Processes in which rubber is employed only to contain the hydraulic fluid are not classified as rubber forming.

Rubber Wheel

A grinding wheel made with a rubber bond.

Rubber-Pad Forming

A sheet metal forming operation for shallow parts in which a confined, pliable rubber pad attached to the press slide (ram) is forced by hydraulic pressure to become a mating die for a punch or group of punches placed on the press bed or baseplate. Developed in the aircraft industry for the limited production of a large number of diversified parts, the process is limited to the forming of relatively shallow parts, normally not exceeding 40 mm (1.5 in.) deep. Also known as the Guerin process. Variations of the *Guerin process* include the *Marforming process*, the *fluid-cell process*, and *fluid forming*.

Rubbers

Cross-linked polymers having glass transition temperatures below room temperature that exhibit highly elastic deformation and have higher elongation.

Rubbing Bearing

A bearing in which the relatively moving parts slide without deliberate lubrication.

Rubbling

Stirring molten metal and or scraping dross from the surface.

Rubidium

A rare metallic element, symbol Rb, atomic weight 85.45, belonging to the group of alkali metals. The chief occurrence of rubidium is in the mineral lepidolite. There is no real rubidium ore, but the element is widely disseminated over the earth in tiny quantities. It is a necessary element in plant and animal life and is found in tea, coffee, tobacco, and other plants. It is silvery-white metal, with a specific gravity of 1.53, a melting point of 102°F (39°C), and boiling at 1270°F (688°C). It takes fire easily in air and decomposes water. Of all the alkali metals, it is next to cesium in the highest chemical activity. It can be obtained by electrolysis and has few industrial applications owing to its rarity. Its chief use is in electronics. For photoelectric cells, it is preferred to cesium, and a very thin film is effective. Like potassium, it has a weak radioactivity by the omission of beta particles, the beta emission being only about one-thousandth that of an equal weight of uranium.

Rubidium Titanyl Arsenate (RTA)

A derivative of potassium titanyl phosphate (KTP), is a nonlinear optical crystal material for improved optical parametric oscillators (OPOs), modulators, and Q-switches. OPOs are used to tune laser frequency; Q-switches are used to control release of laser energy. Because RTA crystals retain clarity with increasing laser power, they can extend a laser's operating transmission range 15% into the infrared. RTA will increase the tunable range of solid-state lasers in industrial, medical, and military applications.

Ruby

A red variety of the mineral **corundum** that ranks with the best grades of precious stones as a gemstone, while the off-color stones are used for watch and instrument bearings. Most of the best rubies, come from upper Myanmar, Thailand, and Cambodia. Before the advent of the synthetic ruby, the larger stones were more viable than diamond. The pink to deep-red colors of the ruby are due to varying percentages of chromic oxide. **Star rubies** contain also a small amount of titania which precipitates along crystallographic planes of the hexagonal crystal and shows as a movable six-ray star when the gem is cut with the axis normal to the base of the stone. **Spinel ruby** is not corundum but magnesium aluminate and is a spinel, often occurring in the same deposits.

Synthetic rubies are equal in all technical qualities to the natural, and synthetic star rubies surpass the natural stones in perfection and quality. Most of the ruby used for instrument bearings is synthetic corundum colored with chromic oxide, since the instrument makers prefer the red color, but the name *ruby* is often applied regardless of color. The U.S. practice in bearing manufacture is to start with a cylindrical rod of the diameter of the desired bearing and to slice to the required thickness. The single-crystal rods are flame polished. For industrial uses, the name *ruby* is often applied to the synthetic material even when it is not red. Synthetic rubies with 0.05% chromium are also used for **lasers**, or light amplifiers, to produce high-intensity light pulses in a narrow beam for communications. Lasers have a wide range of uses, and various other materials are used for specific purposes. Crystals of **potassium dihydrogen phosphate** are used to control the direction of narrow beams of light. The crystal is mounted on the face of the cathode-ray tube.

R

Rubies are also used in **masers** to detect radio signals for space rockets at great distances. The word *maser* means microwave amplification by stimulated emission of radiation. Ruby has the same physical and chemical properties as the sapphire and corundum. But the color inclusions do affect the electronic properties. The *ruby-sapphire crystals* produced by Linde for **optical masers** are grown with a core of ruby and an overlay sheath of sapphire.

The cutting of rubies, sapphires, and other hard crystals into tiny shape bearings was formally a specialized hand industry, and large stocks of cut stones were kept in the National Stockpile for war-time emergencies. But the slicing and shaping of hard crystals are now widely dispersed on a production basis to meet the needs of the electronic industries, and the equipment is regularly manufactured. For example, the *Accu-Cut wheels* of Aremco Products, for slicing and notching crystals and hard electronic ceramics, are metal disks 0.010–0.030 in. (0.025–0.076 cm) thick and 1–4 in. (2.54–10.2 cm) in diameter, with diamond grit metallurgically bonded to the periphery.

Rugosities

See *asperities*.

Ruling Section

The maximum section size of a steel bar that can be fully hardened through to the center by a particular quenching procedure. See *steel* and *hardenability*.

Rumbling

Treating components in a rotating barrel so that they rub against each other and, possibly, other abrasive materials, to remove surface flash or generally improve the surface finish. The same as tumbling except that larger components, and hence more noise may be implied.

Run-In (Noun)

(1) In tribology, an initial transition process occurring in newly established wearing contacts, often accompanied by transients in coefficient of friction, wear rate, or both, that are uncharacteristic of the given tribological system's long-term behavior. (2) In seals, the period of initial operation during which the seal-lip wear rate is greatest and the contact surface is developed.

Run-In (Verb)

In tribology, to apply a specified set of initial operating conditions to a tribological system in order to improve its long-term frictional or wear behavior, or both. The run-in may involve conditions either more severe or less severe than the normal operating conditions of the *tribosystem* and may also involve the use of special lubricants and/or surface chemical treatments. See also *break in* (verb).

Runner

(1) A channel through which molten metal flows from one receptacle to another. (2) The portion of the gate assembly of a casting that connects the sprue with the gate(s). (3) Parts of patterns and finished castings corresponding to the portion of the gate assembly described in (2). See the term *gating system*.

Runner Box

A distribution box that divides molten metal into several streams before it enters the casting mold cavity.

Runner System

All the sprues, runners, and gates through which a plastic material flows from the nozzle of an injection machine or the pot of a transfer mold to the mold cavity. See also *resin transfer molding* and *transfer molding*.

Running-In

The process by which machine parts improve in conformity, surface topography, and frictional compatibility during the initial stage of use. Chemical processes, including formation of an oxide skin, and metallurgical processes, such as strain hardening, may contribute.

Run-Off Plate (of Weld)

Metal attached to the finish position of a weld on which the weld terminates. Its purpose is to provide a site for terminal defects and thereby ensure that full-quality weld is maintained to the end of the main joint. It is normally removed following completion of welding.

Run-On Plate (of Weld)

Metal attached to the start position of a weld on which the weld is initiated. Its purpose is to provide a site for start defects and thereby ensure that a full-quality weld is established by the time the main joint is reached. It is normally removed following completion of welding.

Runout

(1) The unintentional escape of molten metal from a mold, crucible, or furnace. (2) An imperfection in a casting caused by the escape of metal from the mold. (3) In casting, overflow or other excessive leakage from a mold. (4) Of thread. The tapering of a thread to blend into the plain shank of a bolt. (5) Of a test specimen. A specimen that has survived the specified test program without failure. The program may be, for example, a specified number of fatigue cycles or a period of exposure to an environment capable of inducing stress corrosion. See also *axial runout* and *radial runout*.

Runout Table

A *roll table* used to receive a rolled or extruded section.

Rupture

The process of breaking or fracture often in a creep context. There are ill-defined subtleties to the use of this term in a metallurgical context. See *break*. Normally, when linked directly to a damage mechanism, “rupture” implies a break involving significant ductility (contrast with fracture). Hence, the term “creep rupture” is common, but “brittle rupture” would usually be regarded as clumsy. However, it is acceptable, when used in a less precise context, as a synonym for “failure” or “burst” even when a low-ductility failure mechanism

is involved, as in phrases such as “rupture of a pressure vessel by brittle fracture.”

Rupture Data

Creep failure data. See *creep*, *stress rupture*, and *Larson–Miller parameter*.

Rupture Strength

Creep strength.

Rust

The visible corrosion product, ranging in color through red, brown, and yellow formed on iron and steel in oxygenated moist environments. It is largely ferric hydroxide, hydrated iron oxide with a variable composition including FeOH and $\text{Fe}_2\text{O}_3 \cdot \text{H}_2\text{O}$. It is bulky relative to the iron consumed, permeated to moisture, and is readily detached. It is not protective. Some scales on iron such as magnetite can be protective, but these are not formed in moist oxygenated environments. See also *white rust*.

Rust Preventives

Petroleum rust preventives have been used for the temporary preservation of corrodible metal surfaces ever since Colonel Drake discovered the first oil well over 100 years ago. From this first oil, production waxes were separated, refined, and made into “petroleum jelly,” bringing into being the first petroleum rust preventives. The use of petroleum products as protective coatings for oil well equipment spread into all areas requiring low-cost, temporary rust protection.

The raw materials used today are produced in modern petroleum refineries in large volume and low cost. Petroleum has provided a wide range of physical properties required to meet the exacting and varied engineering specifications of the complex industrial and diversified military rust-preventive requirements. These physical properties are viscosity, melting point, pour point, consistency, adhesion, volatility, and density. Chemical additives are usually incorporated with petroleum rust preventatives to improve lubricity, to modify viscosity–temperature relationships, to reduce pour point, to displace water from metal surfaces, to dissolve salts, to prevent foaming, to prevent oxidation of the compound, to impart antiwear properties, to improve detergency and dispersancy, and to prevent corrosion and rusting.

Atmospheric corrosion of ferrous metals accounts for a substantial part of why rust prevention is important and critical. The rust prevention of machined parts presents an overall cost saving because the cost of protection is much less than the cost of cleaning to remove rust, of reprocessing, or of scrapping parts that cannot be salvaged.

Petroleum rust preventatives provide temporary but complete protection against rusting, are easy to apply, easy to remove, and are low in cost. The results of rusting may result in dimensional change, structural weakening, and loss of decorative finish.

Rust-Preventive Types

Petroleum rust preventatives may be conveniently separated into four major types: (1) solid or semisolid waxes, (2) oils, (3) solvent cutbacks, and (4) emulsions.

Solid or Semisolid Waxes

These compounds are generally prepared from combinations of petrolatums and microwaxes with heavy lube oils added to obtain the desired consistency. Three consistencies are specified for military use: hard, medium, and soft.

1. The hard-film grade is applied in the molten state and is intended for long-term, temporary outdoor storage of heavy arms, jigs, and forms, for protecting small metal parts, either packaged or unpackaged, and for long-term indoor storage protection of brightly finished surfaces.
2. The medium-film grade is applied in the molten state or at about ambient temperature by dipping or brushing. It is intended for unshielded outdoor storage in relatively moderate climates at temperatures not exceeding the flow point temperature of the compound.
3. The soft-film grade is applied either by brushing or dipping at room temperature or from the molten state. It is intended primarily for the preservation of friction bearings and for use on machined surfaces indoors or for packaged parts.

Additives may or may not be present, depending on the type of service for which the compound is intended. Several advantages are claimed for the solid type compounds:

1. They form coatings of controllable thickness, they do not drain off during storage, and they provide a substantial physical barrier to both moisture and corrosive gases.
2. They form coatings resistant to mild abrasion, airborne contaminants, and ultraviolet light (sunlight) for extended periods.
3. The fast-setting wax coatings eliminate prolonged draining or drying periods during processing.

There are also several disadvantages:

1. Special thermostatically controlled dip tanks must be used to control thickness.
2. The coating, once removed accidentally during handling, is not self-healing and must be reapplied.
3. The compounds are difficult to remove by wiping or rinsing with solvents. Special facilities must be available for the efficient removal of these hard grades. They are not to be applied to intricate parts or inaccessible surfaces.

Preservative Oils

These are available in as many types as there are special uses for oil-type products. Examples are as follows:

1. Preservative lubricants may contain detergents, pour depressants, bearing corrosion inhibitors, and antioxidants, as well as antirust additives for gasoline or diesel engine use.
2. Special preservative oils for both reciprocating and turbojet aviation engines are available containing nonmetallic (nonashing), antirust additives.
3. Light lubricants for automatic rifles, machine guns, and aircraft, suitable for operation at temperatures as low as -55°C , are available in several viscosity grades.
4. General-purpose preservatives are produced specifically for marine use where salt spray as well as high humidity may rust machinery and shipboard cargo.

R

5. Preservative hydraulic fluids are compounded to preserve hydraulic systems during storage, shipment, and manufacture. These oils contain additives that will permit temporary operational use of the hydraulic systems. In addition to antirust additives, oxidation inhibitors, viscosity index improvers, antiwear agents, and pour depressants are present in hydraulic fluids.
6. Slushing oils are used extensively for the preservation of rolled steel and aluminum sheet rods and bar stock. These oils require careful selection of additives to prevent "black staining" of stacked or rolled sheet. This form of corrosion is a common problem in steel mills.

Metal-conditioning oils are used to loosen and soften scale and rust from heavily corroded surfaces such as marine bulkheads, decks, and structural supports of ballast tanks. These oils appreciably reduce the pitting and general corrosion resulting from the combination of humid atmospheres and frequent immersion in salt water.

Solvent Cutbacks

These are generally of three types and can be applied by spraying, dipping, or slushing. The volatile solvent used in these compounds normally has a flashpoint above 37.8°C and will evaporate completely in several hours leaving the residual protective coating. They include the following:

1. Asphalt cutbacks formulated to dry "to handle" in several hours leaving a smooth black coating approximately 2 mils thick. These coatings are recommended for severe outdoor exposure. They are resistant for several years to salt spray, sunlight, rain, and high humidity.
2. Petrolatum and waxlike coatings that can be either hand and "dry to touch" or soft and easily removed. The dry-to-touch or tack-free coating is usually transparent and provides an excellent preservative coating for spare parts that are stored for long periods indoors and are handled frequently. The soft coatings provide excellent protection against corrosive atmospheres, high humidity, and airborne contamination. These coatings are easily removed by wiping or solvent degreasing but must be protected by protective packaging or storage arrangements. These coatings are not fully self-healing if damaged.
3. Oil coatings are used largely for short-term, in-shop use where parts are still being processed. Humidity protection is provided, with additional emphasis placed on suppression of fingerprint rusting and on displacement of the water remaining from processing.

Emulsifiable Rust Preventives

The emulsifiable rust preventive is an oil or wax concentrate that on proper dilution and on mixing with water will provide a ready-to-use product in the form of an oil-in-water emulsion system. These emulsion systems are fire resistant, provide excellent protection, and are economical. They are intended for use whenever a low-cost, fire-resistant, soft-film, corrosion preventive can be utilized. The compound is formulated to be emulsified in distilled or deionized water, normally at a 1:4 ratio, reducing the volatile content of the corrosion preventive to a minimum. Its fire-resistant properties make it especially adaptable as a substitute for volatile solvent cutbacks where fire hazards increase the expense of application. It has proved efficient for use on small hardware or on parts of uniform contour. Caution should be exercised and applying it to parts of

radical design with cracks, crevices, or depressions, which would prevent adequate drainage and cause subsequent corrosion by trapping excess amounts of water.

Selection of Rust Preventives

The selection of petroleum rust preventatives is based on their temporary nature, ease of application and removal, the economy of providing protection against corrosion, and the type of protection desired (e.g., indoor protection or outdoor exposure).

Indoor Protection

Preservatives of this group must provide a high degree of protection against high humidity, corrosive atmospheres, and moderate amounts of airborne contaminants. Resistance to abrasion is occasionally required where spare parts that are stored in bins or on uncovered racks. Normally, however, the more easily removed products are used, such as oils, soft petrolatums, or soft-film solvent cutbacks.

Outdoor Exposure

Preservatives of this group must withstand the effects of rain, snow, and sunlight as well as provide good resistance to abrasion. The products used for this service are the hard film, asphalt solvent cutbacks, and the hard grades of hot-dip waxes.

Short-Term Storage

These preservatives are commonly used to protect parts between machining operations or prior to final preservation with a heavy-duty product. These light oils or solvent cutbacks usually have fingerprint-suppressing properties to protect the parts during production handling.

Special-Purpose Lubricants

Lubricants for many purposes are formulated to provide primary or secondary rust-prevention properties. These special lubricants include nonashing lubricants for aircraft engine use, high-detergency oils for motor vehicles, low-temperature machine gun or rifle oils, and special salt-spray-resistant lubricating oils for ship-board use.

Functional Uses

Hydraulic oils possessing rust-preventive properties are used during the shipment or storage of equipment containing hydraulic power-transmission systems. This equipment is found in aerospace systems, submarines, aircraft carriers, and industrial machine tools. Various viscosity grades are available.

Rust Proofing

Any surface treatment applied to steel that is claimed to impede or delay rusting.

Ruthenium

A hard silvery-white metal (symbol Ru), ruthenium has a specific gravity of 12.4, a melting point of about 2310°C, and a Brinell hardness of 220 in the annealed state. The metal is obtained from the residue of platinum ores by heat reduction of ruthenium oxide, RuO₂, in hydrogen. Ruthenium is the most chemically resistant of the platinum metals and is not dissolved by aqua regia. It is used as a catalyst to combine nitrogen in chemicals. As ruthenium tetroxide, RuO₄, is

a powerful catalyst for organic synthesis, oxidizing alcohols to acids, ethers to esters, and amides to imides. Ruthenium is a close-packed hexagonal crystal structure. It has a hardening effect on platinum; a 5% addition of ruthenium raises Brinell hardness from 30 to 130 and the electrical resistivity to double that of pure platinum.

Ruthenium is used commercially to harden alloys of palladium and platinum. The alloys are used as electrical contacts (12% ruthenium in platinum) and in jewelry and fountain pen tips. Application of ruthenium to industrial catalysis (hydrogenation of alkenes and ketones) and to automobile emission control (catalytic reduction of nitric oxide) and detection have been active areas of research.

Rutherford Backscattering Spectroscopy

A method of determining the concentration of various elements as a function of depth beneath the surface of a sample, by measuring the energy spectrum of ions that are backscattered out of a beam directed at the surface.

Rutherford Scattering

A general term for the classical elastic scattering of energetic ions by the nuclei of a target material.

Rutile

Rutile is the most frequent of the three polymorphs of titania, TiO_2 , crystallizing in the tetragonal system is the rutile structure type.

The mineral occurs as striated tetragonal prisms and needles, commonly repeatedly twinned. The color is deep blood red, reddish brown, to black, rarely violet or yellow. Specific gravity is 4.2, and hardness 6.5 on the Mohs scale. Melting point is 3317°C . It is synthesized from TiCl_4 at red heat, and colorless crystals are grown by the flame-fusion method, which because of their adamantine luster are used as gem material.

In ceramic applications where titanium oxide is desirable (but where a pure white or certain shades are not required), the more economical rutile is frequently substituted for the pure chemical. Rutile is used to stain pottery bodies and glazes in colors ranging from ivory through yellows to dark tan, according to the amount introduced. Artificial teeth are among the ceramics so tinted.

Rutile is also used in the glass and porcelain enamel industries as a colorant, and to introduce TiO_2 . The largest use of rutile is as a constituent in welding rod coatings.

Rutile Electrodes

See *electrode (welding)*.

r-Value

See *plastic strain ratio*.

RZ Powder

The term iron powder made in Germany from the scale of pig iron.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

S Curve

See *isothermal transformation diagram*.

S/N Curve

A graph plotting stress range (S) against the number of cycles to failure (N) to predict the fatigue life of a material. See *fatigue*.

Sacrificial Protection

Reduction of corrosion of a metal in an *electrolyte* by galvanically coupling it to a more anodic metal; a form of *cathodic protection*.

Saddling

Forming a seamless metal ring by forging a pierced disk over a mandrel (or saddle).

Safe Working Load (S.W.L.)

The maximum load that a component should carry in a normal service. When used in its formal statutory sense, the term recognizes that there is an adequate margin between the safe working load and the *proof load* and a further large margin between the proof load and the breaking load. See *safety factor*.

Safety Critical

Identifies a component or system whose function is vital to the safety of plant operations or the population at large.

Safety Factor

An allowance made by a designer to accommodate unknowns. The factor can be applied to one or more of the properties on which the design is based, including yield, tensile, fatigue or creep strength, and corrosion or erosion rate; see respective entries. For example, a component could be designed on the basis that the expected maximum load will introduce a stress of only a third of the ultimate tensile stress. The safety factor of 3 allows for unpredictable factors such as excessive loading, variation in materials properties, minor manufacturing defects, or deterioration in service. Depending on the particular application, the safety factor may be calculated on the relationship between the expected breaking load at either the safe working load or the proof load. In general, considerations of economy encourage reduction in the safety factor toward unity but this requires increasingly tight quality assurance and accurate prediction and monitoring of service conditions, possibly supported by regular inspection of critical items.

Safety Glass

Glass so constructed, treated, or combined with other materials as to reduce, in comparison with ordinary sheet or plate glass, the likelihood of injury to persons by objects from exterior sources or by these safety glasses when they may be cracked or broken. Types of safety glass include (1) laminated safety glass—two or more pieces of glass held together by an intervening layer or layers of plastic materials. It will crack and break under sufficient impact, but the pieces of glass tend to adhere to the plastic and not to fly. If a hole is produced, the edges are likely to be less jagged than would be the case with ordinary glass; (2) tempered safety glass—a single piece of specially treated plate, sheet, or float glass. When broken at any point, the entire piece immediately breaks into innumerable small pieces, which may be described as granular, usually with no large jagged edges; (3) wire safety glass—a single piece of glass with a layer of meshed wire completely embedded in the glass, but not necessarily in the center of the sheet. It may or may not be ground and polished on both sides. When the glass is broken, the wire mesh holds the pieces together to a considerable extent.

Sag (Metals)

An increase or decrease in the section thickness of a casting caused by insufficient strength of the mold sand of the cope or of the core.

Sag (Plastics)

(1) A local extension (often near the die face) of the parison during extrusion by gravitational forces. This causes necking down of the parison. (2) The flow of a molten sheet in a thermoforming operation.

Sagging (Adhesives)

Run-off or flow-off of adhesive from an adherend surface due to application of excess or low-viscosity material.

Sagging (Ceramics and Glasses)

(1) A defect characterized by bending or slumping of a ceramic article fired at excessive temperature. (2) A process of forming glass by reheating until it conforms to the shape of the mold or form on which it rests. (3) A defect characterized by a wavy line or lines appearing on those surfaces of porcelain enamel that have been fired in a vertical position. (4) A defect characterized by irreversible downward bending in a ceramic article insufficiently supported during the firing cycle.

Sal-Ammoniac

Ammonium chloride, NH_4Cl , sometimes used as a soldering flux.

S

Salt

A salt is a compound formed when one or more of the hydrogen atoms of an acid are replaced by one or more cations of the base. The common example is sodium chloride in which the hydrogen ions of hydrochloric acid are replaced by the sodium ions (cations) of sodium hydroxide. There is a great variety of salts because of the large number of acids and bases that has become known.

Classification

Salts are classified in several ways. One method—normal, acid, and basic salts—depends upon whether all the hydrogen ions of the acid or all the hydroxide ions of the base have been replaced:

Class	Examples
Normal salts	NaCl, NH ₄ Cl, Na ₂ SO ₄ , Na ₂ CO ₃ , Na ₃ PO ₄
Acid salts	NaHCO ₃ , NaH ₂ PO ₄ , Na ₂ HPO ₄ , NaHSO ₄
Basic salts	Pb(OH)Cl, Sn(OH)Cl

The other method—simple salts, double salts (including alums), and complex salts—depends upon the character of completeness of the ionization.

Class	Examples
Simple salts	NaCl, NaHCO ₃ , Pb(OH)Cl
Double salts	KCl, MgCl ₂
Alums	KAl(SO ₄) ₂ , NaFe(SO ₄) ₂ , NH ₄ Cr(SO ₄) ₂
Complex salts	K ₃ Fe(CN) ₆ , Cu(NH ₃) ₄ Cl ₂ , K ₂ Cr ₂ O ₇

In general, all salts in solution will give ions of each of the metal ions; an exception is a complex type of salts such as K₃Fe(CN)₆ and K₂Cr₂O₇.

Any aggregate of molecules, atoms, or ions joined together with a coordinate covalent bond can be correctly called salt; however, by common parlance, the term *salt* usually refers to an electrovalent compound, the classical example of which is sodium chloride.

Salt Bath

A vessel containing molten salts of various compositions. The salt offers rapid and uniform heat transfer with protection against oxidation. Some salts also are intended to carburizing the steel as the first stage of *case hardening*.

Salt Bath Heat Treatment

Heat treatment for metals carried out in a bath of molten salt. See the terms *immersed-electrode furnaces* and *submerged-electrode furnaces*.

Salt Fog Test

An *accelerated corrosion test* in which specimens are exposed to a fine mist of a solution usually containing sodium chloride, but sometimes modified with other chemicals. Also known as salt spray test.

Salting Out

Precipitating a substance in a solution by adding a second substance, usually a salt, without any chemical reaction, such as a double decomposition, taking place.

Saltpeter

Potassium nitrate, KNO₃, a constituent of gunpowder.

Salt Spray Test

Various tests of corrosion rate and stress corrosion susceptibility. Many such tests have been devised with the common factor being that a salt solution is sprayed onto the test specimens for a defined period at regular intervals. The solution is usually sodium chloride up to 20%, and the environment may be open air or an ambient cabinet with environmental control. The test specimens may be unstressed or stressed in tension or bending and may be welds or other joints or bimetals. The test may be predetermined or continued until the test criterion is met. The possible criteria include failure, cracking, corrosion rate, or merely surface appearance. See *salt fog test*.

Samarium

A metallic element, one of the rare earth metals. It has little commercial application.

Sample

(1) One or more units of a product (or a relatively small quantity of a bulk material) withdrawn from a *lot* or process stream and then tested or inspected to provide information about the properties, dimensions, or other quality characteristics of the lot or process stream. (2) A portion of a material intended to be representative of the whole.

Sample Average

The sum of all the observed values in a sample divided by the sample size. It is a point estimate of the population mean. Also known as arithmetic mean.

Sample Median

The middle value when all observed values in a sample are arranged in order of magnitude. If an even number of samples are tested, the average of the two middlemost values is used. It is a point estimate of the population median, or 50% point.

Sample Percentage

The percentage of observed values between two stated values of the variable under consideration. It is a point estimate of the percentage of the population between the same two stated values.

Sample Splitter

A device to divide a metal powder pile for sampling.

Sample Standard Deviation (s)

The square root of the sample variance. It is a point estimate of the population standard deviation, a measure of the “spread” of the frequency distribution of a population. This value of s provides a statistic that is used in computing interval estimates and several test statistics. For small sample sizes, s underestimates the population standard deviation.

Sample Variance (s^2)

The sum of the squares of the differences between each observed value on the sample average divided by the sample size minus 1. It is a point estimate of the population variance.

Sample Thief

A pointed, hollow, tubular device to withdraw a representative metal powder sample from a shipping drum or other packing unit.

Sampling

The process of obtaining a portion of a material that is adequate for making the required tests or analyses and that is representative of that portion of the material from which it is taken.

Sand

Sand is an unconsolidated granular material consisting of mineral or rock fragments between 6.5 μm and 2 mm in diameter. Finer material is referred to as silt and clay, coarser material as gravel. Sand is usually produced by the chemical or mechanical breakdown of older source rocks, but may also be formed by the direct chemical precipitation of grains or by biological processes. Accumulations of sand result from hydrodynamic sorting of sediment during transport and deposition.

Origin and Characteristics

Most sand originates from the chemical and mechanical breakdown, or weathering, of bedrock. Chemical weathering is most efficient to soils, and most sand grains originate within soils. Rocks may also be broken into sand-size fragments by mechanical processes, including diurnal temperature changes, freeze–thaw cycles, wedging by salt crystals or plant roots, and ice gouging beneath glaciers.

Transport

Sand can be transported by any medium with sufficient kinetic energy to keep the grains in movement. In nature, sand is commonly transported by rivers, ocean currents, wind, or ice. Rivers are responsible for transporting the greatest volume of sand over the greatest distances. When rivers deposit sand at the ocean edge, it is commonly remobilized by high-energy breaking waves or transported along the shore by powerful longshore currents. Sand, like coarser and finer sediments, may also be entrained by glacial ice and transported to the sea by glacial flow. Where sand is widely exposed to wind currents, such as in river bars, on beaches, and in glacial outwash plains, it may be picked up and transported by the wind. As it moves, whether subaqueously or subaerially, sand is organized into complex moving structures (bedforms) such as ripples and dunes.

Economic Importance

Sand and gravel production is second only to crushed-stone production among nonfuel minerals in the United States. Although sand and gravel have one of the lowest average per ton values of all mineral commodities, the vast demand makes it among the most economically important of all mineral resources. Sand and gravel are used primarily for construction purposes, mostly as concrete aggregate. Pure quartz sand is used in the production of glass, and some sand is enriched and rare commodities such as ilmenite (a source of titanium) and gold.

Types

An accumulation of grains of mineral matter derived from the disintegration of rocks. It is distinguished from gravel only by the size of the grains or particles but is distinct from clays that contain organic materials. Sands have been sorted out and separated from the organic material by the action of currents of water or by winds across arid lands and are generally quite uniform in size of grains. Usually commercial sand is obtained from riverbeds or from sand dunes originally formed by the action of winds. Much of the earth's surface is sandy, and these sands are usually quartz and other siliceous materials. The most useful commercially are *silica sands*, often above 98% pure. Silica sands for making glass must be free from iron. *Beach sands* usually have smooth, spherical, to ovaloid particles from the abrasive action of waves and tides and are free of organic matter. The white beach sands are largely silica but may also be of zircon, monazite, garnet, and other minerals, and are used for extracting various elements. *Monazite sand* is the chief source of thorium. The *black sands* of Oregon contain chromate, and those of Japan contain magnetite. Kyanite is found in the Florida sands.

Sand is used for making mortar and concrete and for polishing and sandblasting. Sands containing a little clay are used for making molds in foundries. Clear sands are employed for filtering water. Construction sand is not shipped great distances, and the quality of sands used for this purpose varies according to local supply. *Standard sand* is a silica sand used in making concrete and cement tests. The grains are free of organic matter and pass through a 20-mesh sieve, but are retained on a 30-mesh. *Engine sand*, or *traction sand*, is a high-silica sand of 20–80 mesh washed free of soft bond and fine particles, used to prevent the driving wheels of locomotives or cars from slipping on wet rails.

Molding sand, or *foundry sand*, is any sand employed for making molds for casting metals, but especially refers to sands that are refractory and also have binding qualities. Pure silica is ideal for heat resistance, but must contain enough alumina to make it bind together. Molding sands may contain 80% to 92% silica, up to about 15 alumina, about 2 iron oxide, and not more than a trace of lime. Some molding sand contains enough clay or loam to bond it when it is tamped into place. The amount of bond in *Grant sand* and in *Tuscarawa sand* is 17%–18%. About 33% of these natural sands pass through a No. 100 screen, and 20 through a No. 150 screen. The finer the grain, the smoother the casting, but fine-grain sand is not suitable for heavy work because of its impermeability to gases. Sands without natural bonds are more refractory and are used for steel molding. Sands for steel casting must be silica sands containing 90% silica, or preferably 98, and are mixed with 2–10 fireclay. For precision casting, finely ground aluminum silicate is used in the silica sand mixes, and it requires less of a bonding agent.

Zircon sand has high heat resistance and is used for alloy steel casting. *Zircon flour* is finely milled zirconite sand used as a mold wash. *Zirconite sand* for molding is 100–200 mesh in its natural state.

S

It is 70% heavier than silica sand and has a higher heat conductivity that gives more rapid chilling of castings. Common molding sands may contain 5% to 18% of clay materials and may be mixtures of sand, silt, and clay, but they must have the qualities of refractoriness, cohesiveness, fineness of grain, and permeability. To have refractory quality, they must be free of calcium carbonate, iron oxide, and hydrocarbons. *Core sands* also have these qualities, but they are of coarser grain and always require a bond that will bake solidly but will break down easily at the temperature of pouring. Sand with rounded grains is preferred, and the grains must be very uniform in size to prevent filling. When a molding sand is burned out, it is made suitable for reuse by adding bond; but when fireclay is used as a bond, it adheres to the sand grains and that makes it unsuitable for reuse. *Parting sand* is a round-grained sand without bond used on the joints of molds. Foundry parting is usually tripoli or bentonite. Cores are made with sand mixed with core oils. *Greensand cores* are unbaked cores made with molding sand.

Sandblast sand is sand employed in a blast of air for cleaning castings, removing paint, cleaning metal articles, giving a dull, rough finish to glass or metal goods, or renovating the walls of stone or brick buildings. Sandblast sand is not closely graded, and the grades vary with different producers.

Sharp grains cut faster, but rounded grains reduce smoother surfaces. The sand is usually employed over and over, screening out the dust. The dust and fine used sand may be blasted wet. This is known as *mud blasting* and produces a dull finish.

Sandblasting

(1) Abrasive blasting with sand. See also *blasting* or *blast cleaning* and compare with *shot blasting*. (2) Similar to shot blasting extent that sand or other sharp edge mineral grit is used.

Sand Blister/Buckle/Scab

A bulge on the surface of a sand casting. It contains a large proportion of sand mixed with the metal and is easily scraped or chipped off. It results from an area of soft sand being permeated by molten metal.

Sand Castings

Sand casting can be broken down into three general processes: green-sand molding, dry-sand molding, and pit molding. Green-sand molding, in all probability, produces the largest tonnage of castings but is limited in that long, thin projections are very difficult to cast. Dry-sand molds, on the other hand, can produce castings of any desired intricacy (within the normal dimensional limits of the process) because the sand is baked with a binder, increasing the strength of the thin mold sections. Pit molding is the sand process used to make very large, heavy castings.

The Process

Green-Sand Molding

The essential parts of a green-sand mold are pattern, gate, sprue, riser, pouring basin, parting joint, cope, load, pin, drag, and bottom board. The pattern is placed in the flask (consisting of the cope and drag) and molding sand is tightly rammed around it. Usually, the mold is made in two halves, with the pattern lying at the parting line. Removing the pattern from the rammed sand leaves the desired cavity from which the casting is produced. The molder then produces a sprue for pouring metal into the cavity and an opening for a riser to permit air in the cavity to be expelled. Both the sprue and riser also

act as a source of hot metal during solidification and help eliminate shrinkage cavities in the casting. Cores can be added to the mold cavity to shape internal casting surfaces.

Among the advantages of green-sand molding are the following: one pattern can be used to produce any number of castings; most non-ferrous alloys, gray irons, ductile irons, malleable irons, and steel can be cast; and finally, the fragility of the sand cores permits them to collapse after metal is cast around them, thereby eliminating or reducing casting stresses and tendency for hot tearing.

The limitation of the process is its inability to support long, thin projections in the sand.

Dry-Sand Molding

Core boxes, not patterns, are used to make the various parts of the mold. A mixture of sand and a binder is formed in a core box acid baked at 204°C–260°C to harden the sand. The various pieces are then assembled into a mold.

Dry-sand molds, because of the way which they are produced, can be used to make intricate castings. The baking operation strengthens the sand and permits thin projections to be cast without danger of collapsing the mold walls. Cores used in dry-sand molding are collapsible and help reduce hot tearing tendencies.

Pit Molding

If large, intricate parts must be produced, pit molding is considered the most economical production method. (Castings weighing up to 230,000 kg have been produced in pit molds.) Pit molding is a highly specialized operation and the equipment used—sand slingers, molding machines, etc.—precludes the use of much hand labor. The mold usually is dried, increasing sand strength and, consequently, the ability to resist mold erosion during pouring as well as the weight of the casting being poured.

Sand Control

Testing and regulation of the chemical, physical, and mechanical properties of foundry sand mixtures and their components.

Sand Grain Distribution

Variation or uniformity in particle size of a sand aggregate when properly screened by standard screen sizes. See also *grain fineness number*.

Sand Hole

A pit in the surface of a sand casting resulting from a deposit of loose sand on the surface of the mold.

Sandpaper

Originally a heavy paper coated with sand grains on one side, used as an abrasive, especially for finishing wood. Sharp grains obtained by crushing quartz later replaced sand, and the product was called *flint paper*. But most abrasive papers are now made with aluminum oxide or silicon carbide, although the term *sandpapering* is still employed in wood polishing. Quartz grains, however are still much used on papers for the wood industries. For this purpose the quartz grains are in grades from 20 mesh. Good *sandpaper quartz* will contain at least 98.9% silica. The paper used is heavy, tough, and flexible, usually 70 or 80 lb (32 or 36 kg) paper, and the grains are bonded with a strong glue. A process is also employed to deposit the

grains on end by electrostatic attraction so that the sharp edges of the grains are presented to the work.

Sand Reclamation

Processing of used foundry sand by thermal, wet, or dry methods so that it can be used in place of new sand without substantially changing the foundry sand practice.

Sandstone

A consolidated sand rock, consisting of sand grains united with a natural cementing material. The size of the particles and the strength of the cement vary greatly in different natural sandstones. The most common sand in sandstone is quartz, with considerable feldspar, lime, mica, and clay matter. The cementing material is often fine chalcedony. *Silica sandstones* are hard and durable but difficult to work. *Calcareous sandstone*, in which the grains are cemented by calcium carbonate, is called *freestone* and is easily worked, but it disintegrates by weathering. Freestone is homogeneous and splits almost equally well in both directions. *Chert*, formally used as an abrasive and, when employed in building and paving, known under local names as *hearthstone*, *firestone*, and *malmstone*, is a siliceous stone of sedimentary origin. It has a radiating structure and splintery fracture and is closely allied to flint. In color it is light gray to black or banded. The colors of sandstones are due to impurities, pure siliceous and calcareous stones being white or cream-colored. The yellow to red colors usually come from iron oxides, black from manganese dioxide, and green from glauconite. *Crab Orchard stone* of Tennessee is high in silicate with practically no CaO and is often beautifully variegated with red and brown streaks.

Sandstones for building purposes are produced under innumerable names, usually referring to the locality. The *bluestone* of New York State is noted for its even grain and high crushing strength, up to 131 MPa. It contains about 70% silica sand with clay as the binder. *Amherst sandstone* from Ohio contains up to 95% silica with four aluminum oxides and is colored gray and buff with iron oxides. *Flexible sandstone*, which can be bent, comes from North Carolina. It is *itacolumite* and has symmetrically arranged quartz grains which interlock and rotate against one another in a binder of mica and talc.

Holystone is a block of close-grained sandstone, formally used for rubbing down the decks of ships and still used for rubbing down furniture in concrete work. *Briar Hill stone* and *Macstone* are trade names for building blocks consisting of lightweight concrete faced with a slab of sandstone. *Kemrock* is a sandstone impregnated with a black furfural resin and baked to a hard finish. It is used for table tops in chemical equipment to resist acids and alkalies. The term *reservoir rock* refers to friable, porous sandstone that contains oil or gas deposits.

Sand Tempering

Adding sufficient moisture to molding (foundry) sand to make it workable.

Sandwich

Any triple or even multilayer construction. Typically it might comprise outer faces of high-strength durable material and a thick interlayer of low density material with sufficient strength to maintain the bond and spacing between the outer and hence the rigidity of the assembly.

Sandwich Construction

A panel composed of a lightweight core material, such as honeycomb, cellular or foamed plastic, and so forth, to which to relatively thin, dense, high-strength or high-stiffness faces, or skins, are adhered. See the term *honeycomb*.

Sandwich Materials

These are a type of laminar composite composed of a relatively thick, low-density core between phases of comparatively higher density. Structural sandwiches can be compared to I beams. The facings correspond to the flanges; the objective is to place a high-density, high-strength material as far from the neutral axis as possible, thus increasing the section modulus. The bulk of a sandwich is the core. Therefore, it is usually lightweight for high strength-to-weight and stiffness-to-weight ratios. However, it must also be strong enough to withstand normal shear and compressive loadings, and it must be rigid enough to resist bending or flexure.

Core Materials

Core materials can be divided into three broad groups: cellular, solid, and foam. Paper, reinforced plastics, impregnated cotton fabrics, and metals are used in cellular form. Balsa wood, plywood, fiberboard, gypsum, cement-asbestos board, and calcium silicate are used as solid cores. Plastic foam cores—especially polystyrene, urethane, cellulose acetate, phenolic, epoxy, and silicone—are used for thermal-insulating and architectural applications. Foamed inorganic such as glass, ceramics, and concrete also find some use. Foam cores are particularly useful where the special properties of foams are desired, such as insulation. And the ability to foam in place is an added advantage in some applications, particularly in areas that are difficult to reach.

Cellular Cores

Of all the core types, however, the best for structural applications are the rigid cellular cores. The primary advantages of the cellular core are that (1) it provides the highest possible strength-to-weight ratio, and (2) nearly any material can be used, thereby satisfying virtually any service condition.

There are, essentially, three types of cellular cores: honeycomb, corrugated, and waffle. Other variations include small tubes or cones and mushroom shapes. All these configurations have certain advantages and limitations. Honeycomb sandwich materials, for example, can be isotropic, and they have a high strength-to-weight ratio, good thermal and acoustical properties, and excellent fatigue resistance. Corrugated-core sandwich is anisotropic and does not have as wide a range of application as honeycomb, but it is often more practical than honeycomb for high production and fabrication into panels.

Construction

Theoretically, any metal that can be made into a foil and then welded, brazed, or adhesive-bonded can be made into a cellular core. A number of materials are used, including aluminum, glass-reinforced plastics, and paper. In addition, stainless steel, titanium, ceramic, and some superalloy cores have been developed for special environments.

One of the advantages of sandwich construction is the wide choice of facings, as well as the opportunity to use thin sheet materials.

S

The facings carry the major applied loads and therefore determine the stiffness, stability, and to a large extent, the strength of the sandwich. Theoretically, any thin, bondable material with a high tensile or compressive strength-to-weight ratio is a potential facing material. The materials most commonly used are aluminum, stainless steel, glass-reinforced plastics, wood, paper, and vinyl and acrylic plastics, although magnesium, titanium, beryllium, molybdenum, and ceramics have also been used.

Theory

The theory of sandwich materials and functions of the individual components may best be described by making an analogy to an I-beam. The high-density facings of a sandwich correspond to the flanges of the I-beam; the objective is to place a high-density, high-strength material as far from the neutral axis as possible to increase the section modulus without adding much weight. Honeycomb in a sandwich is comparable to the I-beam web that supports the flanges and allows them to act as a unit. The web of the I-beam and honeycomb of the sandwich carry the beam shear stress. Honeycomb and a sandwich differs from the web of an I-beam in that it maintains a continuous area support for the facings, allowing them to carry stresses up to or above the yield strength without crippling or buckling. The adhesive that bonds honeycomb to its facings must be capable of transmitting shear loads between these two components, thus making the entire structure an integral unit.

When a sandwich panel is loaded as a beam, the honeycomb and the bond resist the shear loads while the facings resist the moments due to bending forces, and hence carry the beam bending as tensile and compressive load. When loaded as a column, the facings alone resist the column forces while the core stabilizes the thin facings to prevent buckling, wrinkling, or crippling.

Advantages

The largest single reason for the use of sandwich construction and its rapid growth to one of the standard structural approaches during the past 60 years is its high strength-to-weight or stiffness-to-weight ratio. As an example, consider a 0.6 m span beam with a width of 0.3 m and supporting a load of 1634.4 kg at the midspan. This beam, if constructed of solid steel, would have a deflection of 14.2 mm and weigh 31.15 kg. A honeycomb-sandwich beam using aluminum skins on aluminum cores and carrying the same total load at the same total deflection would weigh less than 3.6 kg. As an interesting further comparison, a magnesium plate to the same specifications would weigh 11.9 kg and an aluminum plate 15.7 kg. Although such clear and simple cases of comparative strength, weight, and stiffness are not normally found in actual designs, it has generally been found that equivalent structures of sandwich construction will weigh from 5% to 80% less than other minimum weight structures and frequently possess other significant advantages.

Other advantages of sandwich construction include extremely high resistance to vibration and sonic fatigue, relatively low noise transmission, either high or low heat transmission depending on the selection of core materials, electrical transparency (varying from almost completely transparent in the case of radome structures to completely opaque in the case of metal sandwich structures), relatively low-cost tooling when producing complex aircraft parts, ability to mass-produce complicated shapes, ability to absorb damage and absorb energy while retaining significant structural strength, and flexibility of design available.

Sandwich Rolling

Rolling two or more strips of metal in a pack, sometimes to form a roll-welded composite.

Sandwich Testing

A method of heating a thermoplastic sheet, prior to forming, that consists of heating both sides of the sheet simultaneously.

S.A.P.

Sintered aluminum powder, usually with reference to material that has been centered then extruded to provide a material with better strength at ambient and elevated temperatures compared with conventionally cast aluminum. The improved properties result from the *dispersion hardening* effect of particles of aluminum oxide from the powder surface.

Saponification

The alkaline hydrolysis of fats whereby a soap is formed; more generally, hydrolysis of an ester by an alkali with the formation of an alcohol and a salt of the acid portion.

Saponification Number

(1) A measure of the amount of constituents of petroleum that will easily *saponify* under test conditions, determined by the number of milligrams of sodium hydroxide that is consumed by 1 g of oil under test conditions. Saponification number is a measure of fatty materials compounded in an oil. (2) A number given to quenching oils that reflects the oils amount of compounding with fatty materials, which thereby helps evaluate the condition of these oils in service. See also *neutralization number* and the term *oil quenching*.

Saponify

(1) To convert into soap. (2) To subject to, or to undergo, saponification.

Sapphire

Sapphire is any gem variety of the mineral corundum (Al_2O_3) except those called ruby because of their medium- to dark-red color. Sapphire has a hardness of 9 (Mohs scale), a specific gravity near 4.00, and refractive indices of 1.76–1.77.

Although blue sapphires are most familiar to the public, sapphires occur in many other colors, including yellow, brown, green, pink, orange, and purple, as well as colorless, and black.

General Nature

Synthetic sapphire, chemically and physically, is the same as the natural mineral, which is now uneconomical to mine because of the low cost of the synthetic ($\$0.05 \text{ g}^{-1}$). It is a single crystal of very high purity aluminum oxide and crystallizes in the hexagonal-rhombohedral crystal system. It has a hardness that is second only to diamond among naturally occurring minerals. It has unusual chemical stability, high thermal conductivity, excellent high-temperature strength, broadband optical transmission, and low electrical loss.

Chemical Properties

Sapphire is inert to most chemical agents. For example, it is not attacked by any acids, including hydrofluoric acid. It is resistant to alkalis and is not attacked by uranium hexafluoride up to 600°C.

Sapphire will dissolve in water at the rate of 1 mg/day at 240 MPa and 700°C. It is also attacked by anhydrous sodium borate–sodium carbonate at 1000°C, by silicon at 1500°C, by sodium hydroxide at 700°C, and by boiling phosphoric acid.

Forms Available and Uses

Synthetic sapphire is available in the form of rods, boule, and disks as well as optical lens shapes. Sapphires are fabricated with diamond grinding techniques into a variety of surface roughnesses, can be optically polished, and can be chemically or flame polished.

Most applications are for watch and instrument bearings, gemstones, phonograph needles, ball pointpen balls, infrared and ultra-violet optics, as well as electronic insulators and masers. Others include orifices, arc lamp tubes, radiation pyrometry, crucibles, film and textile guides, solar cell covers, optical flats, liquid nitrogen heat sinks, klystron windows, and optical filter substrates.

By deliberately adding impurities to the starting material, other modifications of sapphire crystals can be obtained. The most important today is ruby, which is alumina with 0.05% chromium oxide added and is the basic solid-state crystal in microwave and optical maser systems.

The submicron size high-purity alumina powder, which is used as a starting material for producing crystals, is also used as a polishing agent in dentifrice formulation and metallurgical polishing, as supports for high-purity chemical catalyst carriers, and as the raw material in specialty ceramic manufacture.

Satin Finish (Metals)

A diffusely reflecting surface finish on metals, lustrous but not mirrorlike. One type is a *butler finish*.

Satin Finish (Plastics)

A type of finish having a satin or velvety appearance, specified for plastics or composites.

Satin Weave

See *four-harness satin*, *eight-harness satin*, and *harness satin*.

Saturated

- (1) A solution containing the maximum solute content at equilibrium.
- (2) A magnet that is magnetized to the maximum level achievable.

Saturated Calomel Electrode

A *reference electrode* composed of mercury, mercurous chloride (calomel), and a saturated aqueous chloride solution.

Saturation Pressure

The pressure, for a pure substance at any given temperature, at which vapor and liquid, or vapor and solid, coexisted in a stable equilibrium.

Sauter Mean Diameter

The diameter of a liquid droplet that has the same ratio of volume to surface area as the ratio of total volume to total surface area in a distribution of drops, as shown in the following equation:

$$\text{SMD} = \frac{\sum_i n_i d_i^3}{\sum_i n_i d_i^2}$$

where

i is a sampling size interval

d_i is the drop diameter

n_i is the number of drops in that interval

Sauveur's Diagram

A means for estimating the carbon content of annealed carbon steels (maximum of 0.5% manganese) by examining their microstructure to determine the amount of pearlite. The diagram is a straight line plot between 0% and 100% pearlite at eutectoid composition, usually taken as 0.87% carbon, followed by a further straight line falling to 85% pearlite at 1.5% carbon.

Saw Burn

Blackening or carbonization of a cut surface of a pultruded composite material or plastic section. Usually caused by cutting with a dull saw blade, cutting too slowly, or cutting a highly reinforced material with a diamond blade without water.

Saw Gumming

In saw manufacture, grinding away of punch marks or milling marks in the gullets (spaces between the teeth) and, in some cases, simultaneous sharpening of the teeth; in reconditioning of worn saws, restoration of the original gullet size and shape. See the term *sawing*.

Sawing

Using a toothed blade or disk to sever parts or cut contours.

1. *Circular sawing*: Using a circular saw fed into the work by motion of either the workpiece or the blade.
2. *Power band sawing*: Using a long, multiple-tooth continuous band resulting in a uniform cutting action as the workpiece is fed into the saw.
3. *Power hack sawing*: Sawing in which a reciprocating saw blade is fed into the workpiece.

Saybolt Universal Viscosity

A commercial measure of viscosity expressed as the time in seconds required for a 60 mL of fluid to flow through the orifice of the standard Saybolt Universal viscometer (calibrated tube) at a given temperature under specified conditions; used for lighter petroleum products and lubricating oils.

S-Basis

The S-basis property allowable is the minimum value specified by the appropriate federal, military, Society of Automotive Engineers,

American Society for Testing and Materials, or other recognized and approved specifications for the material.

SBR Rubber

SBR synthetic rubbers are versatile, general-purpose elastomers, developed as a substitute for natural rubber during World War II. Known as Buna-S (BU-tadiene, NA-trium, or sodium S-tyrene) in Germany, they were designated GR-S (G-overnment R-ubber S-tyrene) by the United States. The materials have been designated SBR (S-tyrene B-utadiene R-ubber) by the ASTM (American Society for Testing and Materials). They constitute about 80% of domestic synthetic-rubber consumption.

SBR Types

SBR polymers are generally available as dry rubbers (bale or crumb form) and its lattices. So-called hot polymers (polymerized at 50°C), it has been steadily replaced in recent years by the 20%–30% higher tensile, longer-wearing “cold” rubbers (polymerized at 5°C). Cold rubbers generally accept higher pigment loadings than the hot types. The remaining 12% usage of hot polymers is maintained by certain demands for the inherently easier processing characteristics of these materials.

Styrene content varies from as low as 9% and so-called Arctic or low-temperature-resistant rubbers up to 44% in a rubber designed for its excellent flow characteristics. Materials above an arbitrary 50% level are termed plastics, butadiene-styrene, or high-styrene resins. These resins are used as stiffening agents for SBR rubbers in applications such as shoe soles, and the lattices in this composition range are used in the paint industry and paper coating.

Lattices vary in styrene content from 0% to 46%; the higher levels are used where greater strength is needed. Solids vary from 28% to 60%. The higher solids content, large particle size, cold types provide the largest single outlet for SBR lattices as they are rapidly taking over the major share of the natural rubber foam market. Other applications for SBR lattices include adhesives, coatings, impregnating or spreading compounds for rug backing, textiles, and paper saturation.

Physical Properties

With natural and SBR compounds of the same hardness, it is found that the synthetic formulations not only extrude faster, more smoothly, and with a greater degree of dimensional stability, but also with less danger of sticking if the article is to be coiled during curing.

In molded items, SBR compounds are more nearly free of taste and odor than those made with natural rubber.

The inherently superior physical properties of SBR over natural rubber (or those superior characteristics obtainable with special polymers or through compounding of SBR) include the following:

1. Enhanced resistance to attack by organisms (e.g., soil bacteria)
2. Lower compression set
3. Less subject to scorch in curing operations
4. Superior flex resistance
5. Better resistance to animal and vegetable oils
6. Higher abrasion resistance
7. Superior water resistance
8. Lower freeze temperatures
9. Better dampening effect
10. Increased filler tolerance

11. Less high-temperature discoloration
12. Superior aging, including
 - a. Heat resistance (steam or dry heat)
 - b. Sunlight checking
 - c. No reversion or tackiness
 - d. Resistance to oxidation
 - e. Ozone cracking
13. Enhanced electrical insulation properties

Natural rubber excels SBR in building tack, tensile strength, tear resistance, elongation, hysteresis (heating on flexing), and resilience properties.

Although SBR has a higher thermal conductivity than natural rubber, it is not sufficient to overcome its higher hysteresis value. Whereas the low conductivity of natural rubber is an engineering advantage in gaskets or seals used in low-temperature equipment, it becomes a distinct disadvantage in an application such as electrical insulation where overheating at the surface of the conductor is experienced during an overload condition.

Another drawback of the low thermal conductivity of natural rubber is encountered when thick slabs or sections are molded, as the time required to bring the stock up to temperature and reduce it again is excessive. This is particularly significant when the compound used is a hard rubber, containing large amounts of sulfur, which liberate internal heat as well. Although the internal heating factor is not important with soft compounds containing small amounts of sulfur, the polymer content of hard rubber may actually be destroyed by excessive internal temperatures.

Compounding

After selection of the proper polymer from the wide diversity of types available, the compounder is afforded a further latitude in building in desired properties through selection of vulcanizing agents, fillers, deodorants, age resistors, blends of other rubbers and resins, etc.

One of the outstanding differences between natural rubber (*Hevea*) and SBR is the need for reinforcement in the latter. Whereas the *Hevea* tensile strength might be increased 25% with the addition of carbon black from its uncompounded value of about 24.03–27.2 MPa, the tensile strength of SBR is increased to above 20.6 MPa from an initial value of less than 6.9 MPa.

Although not as effective as the carbon blacks, other inorganic fillers including clays, whiting, coated calcium carbonate, and precipitated silicas, barytes, zinc oxide, magnesium, lithopone, and mica are used. Titanium dioxide pigment is used where covering power is desired in white or very brightly colored stocks.

Various degrees of oil resistance may be imparted to SBR compounds (or, put conversely, lower-cost, oil-resistant rubbers can be produced) through blending SBR with the higher-cost neoprene or butadiene-acrylonitrile copolymer rubbers.

Scab

A defect on the surface of a casting that appears as a rough, slightly raised surface blemish, crusted over by a thin porous layer of metal, under which is a honeycomb or cavity that usually contains a layer of sand; defect common to thin-wall portions of the casting or around hot areas of the mold.

Scabbing

(1) In wear, a loosely used term referring to the formation of bulges in the surface. (2) In fracture mechanics, it is identified with *spalling*.

Scaffold

A fused mass of coke and other materials that build up in the shaft of a blast furnace and impede normal downflow of the charge.

Scale (Glass)

A small particle of foreign material embedded in the surface of molded glass articles.

Scale (Metals)

Surface oxidation, consisting of a partially adherent layers of corrosion products, left on metals by heating or casting in air or in other oxidizing atmospheres.

Scale (Plastics)

A condition in which resin plates or particles are on the surface of a pultrusion. Scales can often be readily removed, sometimes leaving surface voids or depressions.

Scale

(1) The material deposited on a surface exposed in pure water. Its primary constituent is mechanically deposited impurities but it may include a percentage of corrosion product. (2) Of a drawing, the ratio of the size as drawn to the size in reality.

Scale Pit

(1) A surface depression formed on a forging due to scale remaining in the dies during the forging operation. (2) A pit in the ground in which scale (such as that carried off by cooling water from rolling mills) is allowed to settle out as one step in the treatment of effluent waste water.

Scaling

(1) Forming a thick layer of oxidation products on metals at high temperature. Scaling should be distinguished from rusting, which involves the formation of hydrated oxides. See also *rust*. (2) Depositing water-insoluble constituents on a metal surface, as in cooling tubes and water boilers.

Scalped Extrusion Ingot

A cast, solid, or hollow extrusion *ingot* that has been machined on the outside surface.

Scalping

Removing surface layers from an *ingot*, *billet*, or *slab* by mechanical or flame cutting techniques of surface defects prior to working an *ingot*, *billet*, or *slab*. See also *die scalping*.

Scandium

Scandium (symbol Sc, element number 21) is as plentiful in the Earth's crust as tungsten and more than cadmium, and it is

considered a rare element because it is so widely distributed that commercial quantities are difficult to obtain.

Chemically, scandium is somewhat similar to aluminum but is more nearly like yttrium and the rare earth metals. It is quite reactive, forming very stable compounds. The halides, however, can be reduced by calcium, sodium, and potassium, and it is in this manner that scandium metal is produced. For example, scandium fluoride is generally reduced with calcium metal in a tantalum or tungsten crucible in an inert atmosphere. As the scandium is purified by distillation at 1650°C–1700°C in a vacuum of 10^{-5} mm Hg. This produces a material with a metallic luster that has a slight yellow tinge but the general appearance of aluminum.

Chemical Properties

Scandium reacts very rapidly with dilute acids but reacts slowly in a mixture of concentrated nitric and hydrofluoric acids owing to the formation of an insoluble layer of scandium fluoride on the surface of the metal.

Scandium metal is quite stable in air at room temperature but oxidizes fairly rapidly at higher temperatures. Scandium oxidizes at a rate of 0.0187, 0.304, and 0.421 mg/cm²/h at 400°C, 600°C, and 800°C, which are very dense, adherent films, while the coatings at 800°C or above are loose and nonprotective.

Fabrication

Scandium metal can be arc-melted in an inert atmosphere such as argon at pressures of 50 mmHg without loss by evaporation. It is extremely active, however, and will “getter” the furnace atmosphere, producing a dark film on the surface of the metal.

Pure scandium can be cold rolled or swaged into thin pieces without annealing if the oxygen content and is kept below 200 ppm. Excessive oxygen occurs as dispersed oxides in the grain boundaries and makes fabrication difficult by causing intergranular cracking.

Metal Preparation and Purification

Scandium is normally prepared by reduction of ScF₃ by heating with calcium or lithium in an inert atmosphere using tantalum crucibles. Unfortunately, molten scandium dissolves up to 5 wt% tantalum, and the metal must be further processed to remove this tantalum. Tungsten is more inert, but tungsten crucibles are seldom used because they are more difficult to fabricate and are more brittle than tantalum.

The as-reduced metal is purified by vacuum-induction melting to remove the more volatile impurities. Then the scandium is distilled away from the residual tantalum and tungsten crucible contamination and other less volatile impurities. The scandium vapor is condensed in a closed-end tantalum tube inverted over the crucible that holds the metal to be purified, and as long as the condensed scandium is not melted, it will not pick up any tantalum. Scandium can be purified by zone refining. But the purest metal is achieved by electrotransport purification of distilled scandium metal.

Uses

The amount of scandium produced and consequently used annually is less than a few hundred kilograms. This is due to a lack of a good source of a raw material containing scandium. If scandium were less costly, much more would be used, but in most applications, other,

S

less-expensive elements are substituted. The demand for scandium has begun to increase and may spur further development of supply.

Metallurgy

Scandium modifies the grain size and increases the strength of aluminum. If added to magnesium together with silver, cadmium, or yttrium, it also strengthens magnesium alloys. Scandium inhibits the oxidation of the light rare earths and, if added along with molybdenum, inhibits the corrosion of zirconium alloys in high-pressure steam.

Ceramics

The addition of 1 mol of ScC to 4 mol TiC has been reported to form the second-hardest material known at the time. Sc_2O_3 can be used in many other oxides and to improve electrical conductivity, resistant to thermal shock, stability, and density. In most of these applications, other rare earth oxides are used because of cost. Laboratory balance knife-edges made from Sc_2O_3 are reported to be better than those made from sapphire.

Electronics

Scandium is used in the preparation of the laser material $\text{Gd}_3\text{ScGa}_4\text{O}_{12}$, gadolinium–scandium–gallium–garnet (GSGG). This garnet when doped with both Cr^{3+} and Nd^{3+} ions is said to be $3\frac{1}{2}$ times as efficient as the widely used Nd^{3+} -doped yttrium–aluminum–garnet (YAG: Nd^{3+}) laser. Ferrites and garnets containing scandium are used in switches in computers, in magnetically controlled switches that modulate light passing through the garnet, and in microwave equipment.

Lighting and Phosphors

The largest use of scandium outside of the research laboratory is probably in high-intensity lights. Scandium iodide is added because of its broad emission spectrum. Bulbs with mercury, NaI, and ScI produce a highly efficient light output of a color close to sunlight. This is especially important when televising presentations indoors or at night. When used with night displays, the bulbs give a natural daylight appearance.

Scandium compounds may be used as host for phosphors or as the activator ion, Sc_2O_3 , ScVO_4 , and its $\text{Sc}_2\text{O}_2\text{S}$ are typical host materials, while ZnCdS_2 activated with a mixture of silver and scandium is a red, luminescent phosphor suitable for use in television. In most cases, other materials are used because of economics.

Compounds

Scandium Carbide

This is a gray powder with a density of 3.59 g/cm^3 and a hexagonal structure that is soluble in mineral acids and has potential as a high-temperature semiconductor.

Scandium Nitride

This gray to red powder with a density of 3.6 g/cm^3 has a face-centered (NaCl) structure. The material is of interest in space technology by virtue of its light weight and high melting point (2700°C). Also, scandium nitride crucibles are used for preparing single-crystal gallium arsenide or phosphide.

Scandium Oxide

This is a lightweight refractory oxide with a melting point of $\sim 2300^\circ\text{C}$. The single-crystal density is 3.91 g/cm^3 with a cubic structure.

Scandium oxide is now prepared in quantity from a variety of sources. It is now routinely separated from certain uranium tailings. Some recovery from beryllium ores can be expected plus potential recovery from some phosphate ores with up to 1%–2% scandium values.

It appears to provide better service than high-alumina compositions. The oxide can be flame-sprayed onto a variety of surfaces where it shows heat and thermal shock resistance superior to zirconia, alumina, and magnesia. Single crystals of the oxide are superior to sapphire for balance knife edges or laser crystal host matrices.

Scanning Acoustic Microscopy (SAM)

The use of a reflection-type acoustic microscope to generate very high resolution images of surface and near-surface features or defects in a material. The images are created by mechanically scanning a transducer with an acoustic lens in a raster pattern over the sample. Compared with conventional ultrasound imaging techniques, which operate in the 1–10 MHz range, SAM is carried out at 100–2000 MHz. See also *scanning laser acoustic microscopy (SLAM)*, *ultrasonic C-scan inspection*, and *ultrasonic testing*.

Scanning Auger Microscopy (SAM)

An analytical technique that measures the lateral distribution of elements on the surface of a material by recording the intensity of their Auger electrons versus the position of the electron beam.

Scanning Electron Microscope

A high-power magnifying and imaging instrument using an accelerated electron beam as an optical device and containing circuitry that causes the beam to traverse or scan an area of sample in the same manner as does an oscilloscope or TV tube. It may utilize reflective (*scanning electron microscopy*) or transmitted (*scanning transmission electron microscopy*) electron optics. This scanning electron microscope provides two outstanding improvements over the *optical microscope*; it extends the resolution limits so that picture magnifications can be increased from $1,000\times$ to $2,000\times$ up to $30,000\times$ to $60,000\times$, and it improves the *depth-of-field* resolution more dramatically, by a factor of approximately 300, thus facilitating its use in fracture studies.

Scanning Electron Microscopy (SEM)

An analytical technique in which an image is formed on a cathode-ray tube whose raster is synchronized with the raster of a point beam of electrons scattered over an area of the sample surface. The brightness of the image at any point is proportional to the scattering by or secondary emissions from the point on the sample being struck by the electron beam.

Scanning Laser Acoustic Microscopy (SLAM)

A high-resolution, high-frequency (10–500 MHz) ultrasonic inspection technique that produces images of features in a sample throughout its entire thickness. In operation, ultrasound is introduced to the bottom surface of the sample by piezoelectric transducer, and the transmitted wave is detected on the top side via rapidly scanning laser beam. Compare with *scanning acoustic microscopy*.

Scanning Transmission Electron Microscopy (STEM)

An analytical technique in which an image is formed on a cathode-ray tube whose raster is synchronized with the raster of a point beam of electrons scanned over an area of the sample. The brightness of the image at any point is proportional to the number of electrons that are transmitted through the sample at the point where it is struck by the beam.

Scantlings

The dimensions of the elements of a structure.

Scarf

See preferred term *edge preparation*.

Scarfing

Cutting surface areas of metal objects, ordinarily by using an oxy-fuel gas torch. The operation permits surface imperfections to be cut from ingots, billets, or the edges of plate that are to be beveled for butt welding. See also *chipping*.

Scarf Joint (Adhesive Bonding)

A joint made by cutting away similar angular segments on two adherends and bonding the adherends with the cut areas fitted together. See also *lap joint*.

Scarf Joint (Welding)

A butt joint in which the plane of the joint is inclined with respect to the main axis of the members.

Scatterband

See *creep*.

Scattering (of Radiant Energy)

The deviations in the direction of propagation of *radiant energy*.

Scattering of x-Rays

In *radiology*, one of the two ways in which the x-ray beam interacts with matter and the transmitted intensity is diminished in passing through object. The x-rays are scattered in a direction different from the original beam direction. Such scattered x-rays falling on the detector do not add to the radiological image. Because they reduce the contrast in that image, steps are usually taken to eliminate the scattered radiation. Also known as *Compton scattering*.

Scavengers

Materials in a flux above a molten metal that combine with contaminants to form slag.

Scavenging

Processes in which some substance, particularly a gas, is added to or bubbled through molten metal to remove dissolved gases or other impurities. The gas may be inert and act purely physically by

allowing the contaminating gas to diffuse into it or, alternatively, it may be active and react chemically with the contaminant.

S.C.F.

Stress concentration factor.

Schaeffler Diagram

A diagram predicting the microstructure of rapidly cooled high chromium nickel stainless steels, in particular welds. The various alloying elements are categorized as austenite formers or ferrite formers and ascribed a factor according to their relative potency compared with nickel or chromium, respectively. The total austenite forming effect is plotted on the vertical axis and the ferrite forming effect on a horizontal. Zones in the diagram then indicate whether the structure will be austenite, martensite, ferrite, or some mixture.

Scheelite

An ore of the metal tungsten, occurring usually with quartz in crystalline rocks associated with wolframite, fluorite, cassiterite, and some other minerals. Scheelite is *calcium tungstate*, CaWO_4 , containing theoretically 80.6% tungsten trioxide and 19.4 lime. It is called *powellite* when it contains some molybdenum to replace a part of the tungsten. It occurs as massive granular or in crystals. The color is white, yellow, brown, or green, with a vitreous luster. *Tungstic acid* is a yellow powder of composition H_2WO_4 made from the ore by treating with HCl. It is not soluble in water but is soluble in alkaline and in hydrofluoric acid, and it is used as a mordant in dyeing, in plastics, and for making tungsten wire by reducing. *Phosphotungstic acid*, called *heavy acid*, is used as a catalyst in difficult synthesis operations on complex ring-compound chemicals. The molecular weight is 2,879, of which three-fourths is tungsten. The three hydrogens produce a strong acid activity. The acid is soluble in water and in organic solvents.

Pure crystals of scheelite suitable for scintillation-counter phosphors for gamma-ray detection are found, but the natural crystal is rare. Calcium tungstate is grown synthetically as a clear, water-white crystal of tetragonal structure in rods and boules with the axis oriented perpendicular to the growth axis of the rod.

Schlieren

Regions of varying refraction in a transparent medium often caused by pressure or temperature differences and detectable especially by photographing the passage of a beam of light.

Schöniger Combustion

A method of decomposition of organic materials by combusting them in a sealed flask that contains a solution suitable for absorbing the combustion products. The flask is swept with oxygen before ignition.

Scintillator

A material that produces a rapid flash of visible light when an x-ray photon is absorbed.

Scleroscope Hardness Test

A dynamic indentation hardness test using a calibrated instrument that drops a diamond-tipped hammer from a fixed height onto the

S

surface of the material being tested. The height of rebound of the hammer is a measure of the hardness of the material.

Scleroscope Hardness Number (HSc or HSd)

A number related to the height of rebound of a diamond-tipped hammer dropped on the material being tested. It is measured on a scale determined by dividing into 100 units the average rebound of the hammer from a quenched (to maximum hardness) and untempered AISI W-5 tool steel test block. See *shore scleroscope*.

Scorification

(1) Oxidation, in the presence of fluxes, of molten lead containing precious metals, to partly remove the lead in order to concentrate the precious metals. (2) Refining of metals, particularly gold and silver and other precious metals.

Scoring

(1) The formation of severe scratches in the direction of sliding. Scoring may be due to local solid-phase welding or to abrasion. In the United States, the term *scuffing* is sometimes used as a synonym for scoring. Minor damage should be called *scratching* rather than scoring. (2) In *tribology*, a severe form of wear characterized by the formation of extensive grooves and scratches in the direction of sliding. (3) The act of producing a scratch or narrow groove in a surface by causing a sharp instrument to move along that surface. (4) The marring or scratching of any form metal part by metal pickup on the punch or die. (5) The reduction in thickness of a material along a line to weaken it intentionally along that line.

Scouring

(1) A wet or dry cleaning process involving mechanical scrubbing. (2) A wet or dry mechanical finishing operation, using fine abrasive and low pressure, carried out by hand or with a cloth or wire wheel to produce *satín* or *butler*-type finishes.

Scouring Abrasive

Natural sand grains or pulverized quartz employed in scouring compounds and soaps, buffing compounds, and metal polishes. Federal specifications require that the abrasive grains used in grit cake soap and scouring compounds all pass a No. 100 screen; the grains for scouring compounds for marble floors must all pass a No. 100 screen, and 95% pass a No. 200 screen. For ceramic floors 90% must pass a No. 80, and 95% must pass a No. 60 screen. Very fine air-floated quartz is employed in metal polishes, and all grains pass a 325-mesh screen, but the extremely fine powders of metal oxides for polishes and fine finishes are generally called *soft abrasives* and are not classified as scouring materials. Same as *abrasion*.

Scragging

The deliberate pre-service straining of components, particularly springs, beyond yield to improve fatigue life. See *autofrettage*, which is a similar technique applied to hollow products.

Scrap

(1) Products that are discarded because they are defective or otherwise unsuitable for sale. (2) Previously used metal that is suitable for reprocessing, usually remounting, into a product of adequate quality. Material rejected or removed during production and return for remelting is often termed *process scrap*. (3) Material discarded or spoiled and not suitable for continued processing to a finished component.

Scraper

An exclusive seal that has metallic or other firm lips or scraping elements. It serves to remove foreign material from a reciprocating shaft.

Scratch

A groove produced in a solid surface by the cutting and/or plowing action of a sharp particle or protuberance moving along that surface.

Scratch Brush

Wire bristle brush.

Scratch Hardness Test

A form of hardness test in which a sharp-pointed stylus or corner of a mineral specimen is traversed along a surface so as to determine the resistance of that surface to cutting or abrasion. The *Mohs hardness* test is among the most widely used forms of scratch hardness tests but is mainly applied to many mineralogical specimens or abrasives. The file hardness test was one of the first scratch hardness tests used for evaluating the hardness of metallic materials. The file test, which involves pressing the flat face of a steel file heat treated to approximately 67–70 HRC against and slowly across the surface to be tested, is useful in estimating the hardness of steels in the high hardness ranges. It provides information on soft spots and decarburization quickly and easily, and is readily adaptable to odd shapes and sizes that are difficult to test by other methods. Other scratch hardness tests involve using diamond cones, pyramids, and spherical tips, but such scratch hardness tests have not been established and standardized to the extent that macro- and microindentation hardness tests have been.

Scratching

(1) In *tribology*, the mechanical removal and/or displacement of material from a surface by the action of abrasive particles or protuberances sliding across the surfaces. (2) The formation of fine scratches in the direction of sliding. Scratching may be due to asperities on the harder slider or to hard particles between the surface or embedded in one of them. Scratching is to be considered less damaging than *scoring*. See also *abrasion*, *plowing*, and *ridging wear*.

Scratching Abrasion

See *low-stress abrasion*.

Scratch-Resistant Coatings

Coating applied to glass surfaces to reduce the effects of frictive damage. Examples are SnO₂ or TiO₂ coatings applied to glass containers.

Scratch Test

Various fairly crude tests in which the component in question is scratched. The two concepts are either that the component is scratched by a series of calibrated implements (see *Mohs test* and *file test*) or it is scratched by a single implement to find variations in hardness.

Scratch Trace

In a metallographic specimen, a line of etch markings produced on a surface at the site of a preexisting scratch, the physical groove of the scratch having been removed. The scratch trace develops when the deformed material extending beneath the scratch has not been removed with the scratch groove and when the residual deformed material is attacked preferentially during etching.

Screen

(1) The woven wire or fabric cloth, having square openings, used in a sieve for retaining particles greater than the particular mesh size. U.S. standard, ISO, or Tyler screen sizes are commonly used. (2) One of a set of sieves, designated by the size of the openings, used to classify granular aggregates such as sand, ore, or coke by particle size. (3) A perforated sheet placed in the gating system of a mold to separate impurities from the molten metal.

Screen Analysis

See *sieve analysis*.

Screen Classification

See *sieve classification*.

Screening

Separation of a powder according to particle size by passing it through a screen having the desired mesh size.

Screw

(1) A screw is a cylindrical body with a helical groove cut into its surface. For practical purposes, a screw may be considered to be a wedge wound in the form of a helix so that the input motion is a rotation while the output remains translation. The screw is to the wedge much the same as the wheel and axle is to the lever in that it permits the exertion of force through a greatly increased distance.

The screw is by far the most useful form of inclined plane or wedge and finds application in the bolts and nuts used to fasten parts together; in lead and feed screws used to advance cutting tools or parts in machine tools, in screw jacks used to lift such objects as automobiles, houses, and heavy machinery; in screw-type conveyors used to move bulk materials; and in the propellers for airplanes and ships. (2) Some versions, wood screws or self-tapping screws, taper so that they can cut their way into unthreaded holes. A machine screw is similar to a bolt in having no taper and requiring a prethreaded hole to enter but it is threaded for the full length of the shank. A drive screw either has a driven member mounted on it or it runs in a fluid to which it imparts motion, termed an Archimedes screw.

Screw Dislocation

A dislocation that travels in a direction normal to the direction of formation of the slip step. See *dislocation*.

Screw-Machined Parts

Among the many screw-machine parts are such things as bushings, bearings, shafts, instrument parts, aircraft fittings, watch and clock parts, pins, bolts, studs, and nuts. Screw-machine parts can be produced at rates up to 4000 parts per hour, and tolerances of ± 0.03 mm are common. In addition, these parts can be made of practically any material that is machinable and that can be obtained in rod form. In comparison, die casting is restricted to a limited number of alloys of relatively low melting point, and cold heading requires materials that are ductile at room temperature.

However, screw-machine parts do have certain limitations: Because the material must be in the form of bar or rod, the cross-section of the part is generally limited to a circle, hexagon, square, or other readily available extruded cross-sections, although a special extruded cross-section can sometimes be ordered. The stock used must be as large as the greatest cross-section of the part, depending on the shape, this may or may not result in large scrap losses. In general, irregular and nonsymmetrical parts are not good screw-machine parts, although some parts of this type are produced.

Parts can become quite expensive unless certain restrictions are observed in selection of material and in design of parts.

Materials

Selection of the material is very important. Cost of producing a part is influenced greatly by ease of machining; poor machinability reduces tool life and causes frequent shutdown to replace tools. If service requirements permit, readily machinable materials, such as resulfurized steels or leaded brasses, should be given preference.

Some of the many metals used in screw-machine parts are carbon and low-alloy steels; stainless and heat-resisting steels; cast and malleable irons; copper alloys, particularly brass, bronze, and nickel-silver; aluminum and magnesium alloys; nickel and cobalt superalloys; and gold and silver. Among the nonmetallic materials used are vulcanized fiber, hard rubber, nylon, Teflon, methyl methacrylate, polyethylene, polystyrene, and phenolics.

Lot Size

Lot size should be considered in selecting the material, as it influences not only the cost of the part but the material that can be used.

Design

Screw-machine parts should be designed to be made from standard compositions, standard stock sizes, and standard shapes. Specifying nonstandard bar not only increases costs but may result in delays in obtaining the parts.

Closer dimensions can be held but should be specified only when necessary, because they increase the cost of producing and inspecting the part.

Holes

Standard drill sizes should be specified if possible. When holes require reaming, sizes that can be finished with standard reamers should be specified.

S

Threads

A major item in the design of a screw-machine product is the selection of a proper standard thread, with the aim of providing interchangeability. In new designs, use the Unified Screw Thread System, adopted by the United States, Canada, and Great Britain. For existing designs, however, continue to use the American National System. Indicate threads by size, pitch, series, and class, only; using a special pitch and specifying major and minor diameters is often unnecessary and always expensive.

Concentricity

When concentricity is required, specify it in terms of total indicator reading (TIR) rather than as a dimension. It is good engineering practice to indicate the diameters that must run true by an arrow leading to a note reading “diameters marked A must be concentric to within—TIR measured at points—.” Specifying concentricity when it is not required increases cost of the part unnecessarily.

Burrs

Do not specify removal of burrs unless this operation is essential. Since there are some doubts about the definition of a burr, the screw-machine industry has established certain criteria:

1. Sharp corners are not considered burrs unless they have ragged edges and interfere with operation of the part.
2. Slight tears or roughness on the first two threads of a tapped hole or the male thread are not burrs unless they interfere with assembly.
3. A projection is not a burr if it must be found with a magnifying glass.

Burrs can be eliminated in most cases without additional cost by specifying chamfered or rounded corners on the parts.

Finish

In general, cost of finishing will depend on the degree of finish required; the finer the finish, the higher the cost. A finish for appearance only need not be as fine as a finish required on mating or bearing surfaces. In any case, finish should be specified in terms of microinch root-mean-square (rms) units. Microinch finish depends on material and operation and without secondary operations can range from the usual 125 rms to as low as 16 rms. The latter finish requires special care and is a very high cost operation on a production basis.

Dimensions

If a part requires heat treatment or plating, dimensions supplied to the part producer will depend on where these operations are to be done. If the supplier is to finish the part, give dimensions to apply after heat treatment or plating; if the buyer is to finish the part, give dimensions to apply before heat treating or plating.

Screw Plasticating Injection Molding

A technique in which the plastic is heated and converted from pellets to a viscous melt, and then forced into a mold by means of an extruder screw, which is an integral part of the molding machine.

Machines are either single stage, in which plastication and injection are done in the same cylinder, or double stage, in which the material is plasticated in one cylinder and then fed to a second for injection into a mold. See also *injection molding* (plastics).

Screw Press

A high-speed press in which the ram is activated by a large screw assembly powered by a drive mechanism.

Screws

See *extruder* (plastics).

Screw Stock

(1) Free-machining bar, rod, or wire. (2) A common term for steels and nonferrous metals, notably brass, having superior machinability and used to make screws and small turn parts on automatic screw machines. In steels, free-cutting, or free-machining, quality is imparted by the addition of small amounts of alloying elements, such as sulfur, phosphorus, lead, tellurium, bismuth, calcium, or selenium, sometimes in various combinations. In brass, lead is the usual free-machining additive.

Scrim

A low-cost reinforcing fabric for composites made from continuous filament yarn in an open-mesh construction. Used in the processing of tape or other *B-stage* material to facilitate handling.

Scruff

A mixture of tin oxide and iron-tin alloy formed as dross on a tin-coating bath.

Scuffing

(1) Localized damage caused by the occurrence of solid-phase welding between sliding surfaces, without local surface melting. In the United Kingdom, scuffing implies local solid-phase welding only. In the United States, scuffing may include abrasive effects and the term *scoring* is sometimes used as a synonym. (2) A mild degree of *galling* that results from the welding of asperities due to frictional heat. The welded asperities break, causing surface degradation. In general, the term *scuffing* has been used in so many different ways that its use should be avoided whenever possible, and instead replaced with a more precise description of the specific type of *surface damage* being considered. (3) Light surface damage by a mechanical rather than a corrosion process. The term is used for the early stage of both *adhesive wear* and *abrasive wear*.

Sea Coal

Finely ground coal, used as an ingredient in molding sands.

Seal

(1) In tribology, a device designed to prevent leakage between relatively moving parts. (2) A device designed to prevent the movement of fluid from one chamber to another, or to exclude contaminants.

Sealant

A material applied to a joint in paste or liquid form that hardens or cures in place, forming a seal against a gas or liquid entry. The primary application area for sealants is the building construction industry. Sealants for the commercial construction market are designed to act as a barrier to water, air, atmospheric pollution, vibration, insects, dirt, and noise, while compensating for movement that occurs in the structure being sealed. This movement can be caused by many factors, including changes in temperature and moisture content, permanent loading or load transfer, and chemical changes such as sulfate attack and wind loads. Other key sealant markets are the automotive industry, the aerospace market, and the electrical and electronics market. Major sealant types include oil-base caulks (25%–30% linseed or soy oil, 6%–12% fibrous filler, 40%–60% calcium carbonate filler, 0.05%–3% pigment, 0%–2% gelling agents, and 0%–1% catalyst), latex acrylic polymers, polyvinyl acetate caulks, solvent acrylics, butyl sealants, polysulfites, urethanes, and silicones.

Seal Coat (Thermal Spraying)

Material applied to infiltrate the pores of a thermal sprayed deposit.

Sealing

- (1) Closing pores in anodic coatings to render them less absorbent.
- (2) Plugging leaks in a casting by introducing thermosetting plastics into porous areas and subsequently setting the plastic with heat.

Sealing Face

The lapped surface of a seal that comes in close proximity to the face of the mating ring of a face seal, thus forming the primary seal. With reference to lip seals, the preferred term is seal contact surface.

Seal Nose

The part of the primary seal ring of a face seal that comes in closest proximity to the mating surface and that, together with the mating surface, forms the primary seal.

Seal Oil

An oil resembling sperm oil obtained from the blubber of the *oil seal*, a sea mammal native to the Atlantic Ocean. The oil has a saponification value as high as 195 and an iodine value up to 150, and it was once valued for lubricating and cutting oils but is now scarce.

Some seal oil is obtained from Steller's sea lion, a large-eared seal found from southern California to the Bering Sea. The adult male weighs up to 2200 lb (998 kg). The blubber is about 75% oil, with an iodine value of 143 and saponification value of 190. From 40% to 50% of the carcass is a dense, dark-red, edible meat, but in the United States, *seal meat* is used only in animal foods. *Seal leather*, from the skin, is used for fancy specialty articles, but it has too many defects for general use. The product known as *sealskin* is a valuable fur skin from the fur seal, about 80% of which are caught off the Pribilof Islands where they return in June to breed. No killing is now permitted at sea. Each bull seal has as many as 50 females, and the killing is usually restricted to the surplus males. About 30% of the skins are black fur, which brings the highest price.

Sealing Processes

Various processes intended to improve the surface condition, particularly its resistance to fluid penetration but also its resistance to staining or tarnishing. Examples include coating with oil, grease, silicone, paraffin/lanoline mixtures, etc., immersing newly anodized coatings in boiling water to block the natural pores with the resultant aluminum hydroxide, pressure or vacuum impregnation of porous casings with resins and phosphate conversion coatings.

Sealing Run (of Weld)

The run laid on the remote side of a previously welded root. Compare with *seal weld*.

Seals (Ceramic-to-Metal Seals)

The resultant fabrication after brazing depends on the integrity of the seal. Application in electronics demands that the seal withstand high vacuum and that the materials used in its fabrication do not outgas to poison the vacuum. There are several types of ceramic-to-metal seals.

Butt Seals

A flat metal washer brazed to a flat metallized ceramic surface is typical of this class. The principal stress is a shear stress that may break the ceramic in brittle fracture. Ceramic backup rings are frequently used to establish a uniform stress distribution, which materially improves the ruggedness of the joint. Ductility of the braze and of the metal hardware is also significant.

External Seals

A flange, or collar, surrounding a cylindrical ceramic part is typical of this class. The metal is selected for its slightly higher coefficient of expansion and it produces the resultant seal.

Glass-to-Metal Seals

The coefficient of linear expansion of the glass is matched as closely as possible to that of the metal it is to join. Both materials are heated prior to forming the seal; the glass to flowing and the metal to a dull red heat. A thin oxide coating on the metal often is needed for good adhesion.

Internal Seals

The seals can be very reliable if a low-expansivity metal (e.g., tantalum) can be used for the lead. Low-expansion metals result in compressive stresses but their poor oxidation resistance frequently precludes their use. Kovar and nickel-iron alloys, plus the high expansivity braze metals, ordinarily result in tensile stresses at the inner wall of the ceramic. As a ceramic is weakest in tension, this design may be troublesome unless properly engineered.

Ram Seal (Crunch Seal)

The metal sleeve with a soft plating such as copper, silver, or nickel is distorted while moving over the sharp ceramic edge. Ceramic-metal contact is limited to a thin circumferential line.

S

Taper Seal (Telescoping Seal)

A thin metal sleeve is forced onto a thick ceramic cylinder whose outside diameter is tapered. Negligible stresses are introduced into the ceramic but the metal may be stressed beyond its yield point. During thermal cycling, the metal may fail through fatigue.

Seal Weld

A weld that forms a continuous impervious barrier to fluid but with no significant contribution to joint strength. Compare with *sealing run*.

Seam

(1) On a metal surface, an unwelded fold or lap that appears as a crack, usually resulting from a discontinuity. (2) A surface defect on a casting related to but of lesser degree than a *cold shut*. (3) A ridge on the surface of a casting caused by a crack in the mold face. (4) A defect in the form of an elongated, surface emergent fissure produced during working operations. (5) Any linear joint formed by soldering, welding, folding, etc.

Seamless Tubing

Tubing that does not contain a longitudinal or helical seam weld. It may be made by various processes including various processes such as *tube making* and *extrusion*.

Seam Weld

A continuous weld made between or upon overlapping members, in which coalescence may start and occur on the faying surfaces, or may have proceeded from the surface of one member. The continuous weld may consist of a single weld bead or a series of overlapping spot welds. Common seam weld types include (1) lap seam welds joining flat sheets, (2) flange-joint lap seam welds with at least one flange overlapping the mating piece, and (3) mash seam welds with work metal compressed at the joint to reduce joint thickness. See also *roller spot welding*.

Seam Welding

(1) Arc or resistance welding in which a series of overlapping spot welds is produced with rotating electrodes or rotating work, or both. (2) Making a longitudinal weld in sheet metal or tubing. See also *resistance seam welding*.

Season Cracking

An obsolete term for stress corrosion cracking in brass. The term is said to derive from the spontaneous cracking, during the Indian monsoon season, of brass cartridges containing significant residual stress and stored in the ammonia-rich environment of stables.

Seasoning

Various circumstances where a product is left to develop some characteristic over a period of time.

Seaweed

A plant growing in the sea, belonging to the extensive plant division known as *algae*. About 17,000 varieties of seaweed are listed, but

only a few are exploited commercially. Algae are non-seed-bearing plants containing photosynthetic pigments. They have no vascular or food-conveying system and must remain submerged in the medium from which they acquire their food. They occur in both fresh and salt waters.

The *brown seaweeds*, which are the true kelps, grow in temperate and polar waters. They produce *algin*, *fucoidin*, and *laminarin*. The *red seaweeds* are the *carrageens*, which reduce *carrageenan*, and the *agarophytes*, which yield *agar* and *agaroid*. They grow in warm waters. But color is an indefinite classification; the chlorophyll in the green Irish moss is often so masked by other pigments that the weed may be purplish black. All the seaweed colloids, or phycocolloids, are polysaccharides, having galactose units linked in long chains of molecular weights from 100,000 to 500,000, varying in their chemical structure. They are anionic polyelectrolytes, with negative radicals on each repeating polymer unit. *Irish moss*, also called *chondrus*, *pearl moss*, and *carrageen*, is a dwarf variety of brown seaweed.

The seaweed of the north Atlantic is also used to produce agar and algin. It is bleached and treated to produce gelatin used in foodstuffs, as a clarifying agent, and as a sizing for textiles. It is a better suspending and gelatinizing medium than agar for foodstuffs and cosmetic emulsions. At least 25 mineral salts are known to be present in seaweed as well as several vitamins. In the utilization of the seaweed as gelatin or alginate, these are left in the *kelp meal*, which is marketed as poultry and stock feed. In Asia, the whole plant is cooked and eaten. *Seaweed flour*, made in Germany from *Iceland seaweed*, is the ground, dry seaweed containing all the minerals and vitamins. It is mixed with wheat and rye flours to make *algenbrot*, a bread with higher food value and better keeping qualities than ordinary wheat bread. But more than 8% gives a peculiar flavor to the bread. The Irish name *dulse* is applied to the dried or cooked seaweed, used in the Canadian Maritime Provinces for food. It is purple and rich in iodine and mineral salts. Other species, known as *laver* and *murlins*, are also used in Iceland, Ireland, and Scotland for food. When used for producing iodine in Scotland, the seaweed goes under the general name of *tangle*.

Dry seaweed contains up to 30% *alginic acid*; the water-soluble salts of this acid are called algin. It belongs to the group of complex, open-chain *uronic acids* that occur widely in plant and animal tissues and are related to the proteins and pectins. All the alginates are edible, but they pass unchanged through the alimentary tract and add no food value. Carrageenan is much used as a stabilizer for chocolate in milk. Laminarin is used as *laminarin sulfate* as a blood-clotting agent. *Sodium alginate* is used as a stabilizer and ice-crystal retarder in ice cream, as an emulsifier in medicines, and to replace gum arabic, a colorless, water-soluble gum made by dissolving algin in sodium carbonate solution and neutralizing with hydrochloric acid. *Protan jelly*, used for coating fish for freezing, is algin in a dilute edible acid. When frozen, the jelly is impervious to air and prevents oxidation. It can be washed off with water.

Alginic fibers are silklike fibers made by forcing a sodium alginate solution through spinnerets into a calcium chloride bath and insolubilizing with beryllium acetate, but the fiber is soluble in sodium soaps and the fabrics must be dry-cleaned. Soluble alginic yarns are used for making fancy fabrics where uneven spacing of threads is desired without change in the loom. The alginate yarn is washed out of the fabric after weaving, leaving the desired spacing.

Secant Modulus

(1) The slope of the secant drawn from the origin to any specified point on the stress-strain curve; see also *modulus of elasticity*. (2) The ratio of stress to strain, analogous to the elastic modulus,

for cases where the stress strain relationship is not linear; see *tensile test*. The secant modulus ignores nonlinearity by calculating a specific value for each measured combination of stress and strain.

Secondary Alloy

Any alloy whose major constituent is obtained from recycled scrap metal. Compare with *primary alloy*.

Secondary Bonding

The joining together, by the process of adhesive bonding, of two or more already cured composite parts, during which the only chemical or thermal reaction occurring is the curing of the adhesive itself.

Secondary Bonds

The weaker interatomic bonds such as the van der Waals force.

Secondary Circuit

The portion of a welding machine that conducts the secondary current between the secondary terminals of the welding transformer and the electrodes, or electrode and work.

Secondary Creep

This stage of creep during which the rate of creep deformation is constant, assuming constant stress. See *creep*.

Secondary Crystallization

In processing of plastics, the slow crystallization process that occurs after the main solidification process is complete. Often associated with impure molecules.

Secondary Electron

A low-energy electron (0–50 eV) emitted from a surface that is struck by particles with higher energies.

Secondary Etching

Development of microstructures deviating from the primary structure of a metal or alloy through transformation and heat treatment in the solid state.

Secondary Extinction

In *x-ray diffraction*, a decrease in the intensity of a diffracted x-ray beam caused by parallelism or near-parallelism of mosaic blocks in a mosaic crystal; the lower blocks are partially screened from the incident radiation by the upper blocks, which have reflected some of it. See also *primary extinction*.

Secondary Gas

In thermal spraying, the gas constituting the minor constituent of the arc gas fed to the gun to produce the plasma. The primary arc gas, usually argon or nitrogen, is supplemented with secondary gases such as nitrogen, helium, and/or hydrogen, in order to increase the temperature of the plasma.

Secondary Hardening

The hardness increase in some alloy steels produced by tempering. It results from carbide precipitation effects plus, in some cases, the transformation to martensite of retained austenite following the reduction of its carbon content by the carbide precipitation. See *steel*.

Secondary Ion

An ion other than the probe ion that originates from and leaves the specimen surface as a result of bombardment with a beam of primary or probe ions; a sputtered ion. See also *sputtering*.

Secondary Ion Mass Spectroscopy (SIMS)

An analytical technique that measures the masses of ions emitted from the surface of a material when exposed to a beam of incident ions. The incident ions are usually monoenergetic and are all of the same species, for example, 5 keV Ne⁺ ions. See also *secondary ion*.

Secondary Metal

Metal recovered from scrap by remelting and refining.

Secondary Nucleation

In processing of plastics, the mechanism by which crystals grow.

Secondary Operation

Any operation performed on a sintered powder metallurgy compact, such as sizing, coining, repressing, impregnation, infiltration, heat or steam treatment, machining, joining, plating, or other surface treatment.

Secondary Phases

Phases in alloy systems that do not include the pure metal in their range, that is, all phases in a system other than the two primary phases.

Secondary Recrystallization

The process by which a few large grains are nucleated and grow at the expense of a fine-grained, but essentially strain-free matrix. Also known as abnormal or discontinuous grain growth. See also *primary recrystallization*.

Secondary Seal

A device, such as bellows, piston ring, or O-ring, that allows axial movement of the primary seal of a mechanical face seal without undue leakage.

Secondary-Standard Dosimetry System

A system that measures energy deposition indirectly. It requires conversion factors to account for such considerations as geometry, dose rate, relative stopping power, incident energy spectrum, or other effects, in order to interpret the response of the system. Thus, it requires calibration against a primary dosimetry system or by means of a standard radiation source. See also *dosimeter*.

S

Secondary Stresses

(1) Bending stresses as opposed to direct tensile stresses. (2) Additional stresses superimposed on the main stress.

Secondary Structure

In aircraft and aerospace applications, a structure that is not critical to flight safety.

Secondary x-Rays

The x-rays emitted by a specimen following excitation by a primary x-ray beam or an electron beam.

Second-Degree Blocking

In adhesive bonding, an adherence of such degree that when surfaces under test are parted, one surface or the other will be found to be damaged.

Second-Phase Inhomogeneity

In ceramics and glasses, a microstructural irregularity related to the nonuniform distribution of a second phase, for example, an atypically large pocket of a second phase or a second-phase zone of composition or crystalline phase structure different from the matrix material.

Sectioning

The removal of a conveniently sized representative specimen from a larger sample for medley graphic inspection. Sectioning methods include shearing, *sawing* (using hack saws, band saws, and diamond wire saws), abrasive cutting, and *electrical discharge machining*.

Sedimentation

The settling of particles suspended and dispersed in a liquid through the influence of an external force, such as gravity or centrifugal force.

Seebeck Effect

The electromotive force (e.m.f.) due to the difference of temperature between two junctions of dissimilar conductors in a circuit. See also *thermoelectric effect*.

Seed

(1) A small, single crystal of a desired substance added to a solution to induce crystallization. (2) Small particles or agglomerates, crystals, or crystallites introduced in large numbers into a vessel to serve as nuclei or centers for further growth of material on their surfaces. (3) An extremely small gaseous inclusion in glass.

Seeger Cone

Tall, narrow pyramids (about 8°–10° slope) of fireclay and refractory mixtures having compositions selected to cause the pyramid

to collapse at some specific temperature. They are used usually in multiples covering a range of temperature to monitor the peak temperature in furnaces.

Segment

In *sampling*, a specifically demarked portion of a *lot*, either actual or hypothetical.

Segment Die

A die made of parts that can be separated for ready removal of the workpiece. Synonymous with *split die*.

Segregation (Metals)

(1) Nonuniform distribution of alloying elements, impurities, or microphases in metals and alloys. (2) A casting defect involving a concentration of alloying elements at specific regions, usually as a result of the primary crystallization of one phase with the subsequent concentration of other elements in the remaining liquid. Microsegregation refers to normal segregation on a microscopic scale in which material richer in an alloying element freezes in successive layers on the dendrites (*coring*) and in constituent network. Macrosegregation refers to gross differences in concentration (e.g., from one area of a casting to another). See also *inverse segregation* and *normal segregation*.

Segregation (Plastics)

A separation of components in a molded article usually denoted by wavy lines and color striations in thermoplastics. In thermoset plastics, usually a separation of resin and filler on the surface.

Segregation

Variations in impurity and alloy content across a grain or casting. The effect arises because the first metal to solidify is usually relatively pure so impurities and alloying elements tend to be rejected into the band of material immediately ahead of the advancing solidification front. Within a grain, significant alloy composition gradients can occur—termed *Coring*. On a larger scale, when advancing grains meet, impurities pushed ahead of the two grains concentrate at the grain boundaries—termed *minor segregation*. If solidification continues progressively from the periphery to the center of the ingot, impurities and the alloy constituents tend to become concentrated near the center line. This is called *normal segregation*, *major segregation*, or *V segregation*, the latter reflecting the characteristic distribution of the impurities revealed by sectioning the ingot. In large ingots, the impurity level in the band of molten metal ahead of the solidification front may depress its freezing point to such an extent that the purer metal at the center of the ingot solidifies first, leaving a band of impurities at about mid radius. This is termed *inverted V segregation*, again because of its appearance on sectioning. In extreme cases, material rich in low-melting-point alloy can be squeezed back along and solidify grain boundaries toward or onto the exterior surface, termed *inverse segregation*. Eruptions of this low-melting-point, alloy-rich material onto the surface are termed *blebs* or *blebbing* or *cauliflowers*.

Segregation Banding

Inhomogeneous distribution of alloying elements aligned in filaments or plates parallel to the direction of working. See also the term *banding*.

Segregation (Coring) Etching

Development of segregation (coring) mainly in macrostructures and microstructures of castings.

Seize

To prevent a metal part from being ejected from a die as a result of *galling*.

Seizing/Seizure/Seize-Up

(1) An extreme case of adhesive wear when the two contacting surfaces become permanently locked together. The engagement mechanism may be purely mechanical, resulting from mutual distortion and embedding of the two surfaces or there may be a measure of welding, perhaps considerable, resulting from the high local temperature generated by friction. (2) The stopping of relative motion as a result of interfacial friction. Seizure may be accompanied by gross surface welding. The term is sometimes used to denote *scuffing*. See also *solder lock*.

Séjournet Process

The use of glass as lubricant during extrusion at high temperature, particularly of steels. Immediately prior to entering the extrusion chamber, the heated billet is coated, typically by rolling it down a tray of powder, and a bonded pad of powder is placed in the die end of the chamber. See *Ugine-Séjournet process*.

Selected-Area Diffraction (SAD)

Electron diffraction from a portion of a sample selected by inserting an aperture into the magnification portion of the lens system of a transmission electron microscope. Areas as small as 0.5 μm in diameter can be examined in this way.

Selected Area Diffraction Pattern (SADP)

An electron diffraction pattern obtained from a restricted area of a sample. The sharp spots in the pattern correspond closely to points in the reciprocal lattice of the material being studied. Usually such patterns are taken from a single crystal or a small number of crystals. Any of the three types of electron diffraction patterns can be generated in an SADP: (1) ring patterns from fine-grained polycrystalline materials in which diffraction occurs simultaneously from many grains with different orientations relative to the incident beam; (2) spot patterns in which diffraction occurs from a single-crystal region of the specimen; and (3) Kikuchi line patterns in which diffraction occurs from a single-crystal region of the specimen, which is sufficiently thick that the diffracting electrons have undergone simultaneous elastic and inelastic scattering. See the term *diffraction pattern* and *Kikuchi lines*.

Selective Block Sequence

A block welding sequence in which successive blocks are completed in a certain order selected to create a predetermined stress pattern. See also the term *block sequence*.

Selective Freezing

When an alloy phase with a wide composition range commences to solidify the first crystals are considerably enriched with the higher melting point constituent. These may be selectively removed for use or to be discarded.

Selective Heating

Intentionally heating only certain portions of a workpiece.

Selective Leaching

(1) Corrosion in which one element is preferentially removed from an alloy, leaving a residue (often porous) of the elements that are more resistant to the particular environment. Also called *dealloying* or *parting*. (2) The dissolution and removal of one component from a mixture that may be an ore or other mix of powders or it may be a solid alloy. The term is sometimes used as a generic term for corrosion processes such as dezincification in which one element of an alloy is removed. However, purists may argue that dezincification and similar processes involve solution of both elements followed by redeposition of the survivor. See also *decarburization*, *decobaltification*, *denickelification*, *dezincification*, and *graphitic corrosion*.

Selective Quenching

Quenching only certain portions of an object.

Selective Transfer

A process involving the transfer and attachment of a specific species from one surface to the mating surface during sliding. This term is to be distinguished from the general tribological term *transfer*, which involves the same general process, but which, when used by itself, does not discriminate as to which of the species present as a multiconstituent surface is transferred during sliding.

Selectivity

In materials characterization, the ability of a method or instrument to respond to a desired substance or constituent and not to others.

Selenium

Selenium (symbol Se) is the third member of group VIB of the periodic arrangement of the elements; it is more metallic than sulfur but less metallic than tellurium, the two adjacent elements of this group.

It is rarely found in its native state but is usually associated with lead, copper, and nickel from which it is recovered as a by-product.

Chemical Properties

The chemical properties of selenium are very similar to other group VIB elements such as sulfur and tellurium. It reacts readily with

S

oxygen and halogens to form their respective compounds, that is, oxides and halides. Selenous and selenic acids are easily prepared and in many respects resemble sulfurous and sulfuric acids. Selenium is not very soluble in aqueous alkali solutions, but selenites and selenates are readily prepared by fusion with oxidizing salts of the alkalies.

Selenium metal is odorless and tasteless, but the vapor has a putrid odor. The material was highly poisonous, and is used in insecticides and ship-hull paints. Foods grown on soils containing selenium may have toxic effects, and some weeds growing in the Western states have high concentrations of selenium and are poisonous to animals eating them. Selenium burns in air with a bright flame to form selenium dioxide, SeO_2 , which is in white, four-sided, crystalline needles. The oxide dissolves in water to form selenous acid, H_2SeO_3 , resembling sulfurous acid but very weak.

Forms

Commercial grades (99.5%) of selenium are usually sold as a powder of various mesh sizes packed in steel drums. High-purity selenium (99.99%), used primarily in the electronics industry, is available as small pellets.

Ferroselenium containing 50%–58% selenium and nickel-selenium containing 50%–60% selenium are available in the form of metallic chunks packed in wooden barrels or boxes.

Applications

The most important uses for selenium are in the electronics industry, and such components as current rectifiers, photoelectric cells, xerography plates, and as a component in intermetallic compounds for thermoelectric applications.

A selenium dry-plate rectifier consists of a base plate of aluminum or iron, either nickel plated or coated with a thin layer of bismuth; a layer of 0.05–0.08 mm of halogenated selenium; an artificial barrier layer; and a counter-electrode of cadmium or a low-melting alloy. The purpose of a controlled amount of halogen in the selenium is to accelerate the transformation from amorphous to the hexagonal form, which is done at temperatures slightly above 210°C during the manufacturing process.

The photoelectric properties of selenium make it useful for light-measuring instruments and for electric eyes. Amorphous or vitreous selenium is a poor conductor of electricity, but when heated, it takes the crystalline form, its electrical resistance is reduced, and it changes electrical resistance when exposed to light. The change of electric conductivity is instantaneous; even the light of small lamps has a marked effect since the resistance varies directly as the square of the illumination. The pure amorphous powder is also used for coating nickel-plated steel or aluminum plates in rectifiers for changing alternating current to pulsating direct current. The coated plates are subjected to heat and pressure to change the selenium to the metallic form, and the selenium coating is covered with a layer of cadmium bismuth alloy. Selenium rectifiers are smaller and more efficient than copper oxide rectifiers, but they require more space than silicon rectifiers and are limited to an ambient temperature of 85°C.

Selenium is also used in steels to make them free-machining, with up to 0.35% used. Up to 0.05% of selenium may also be used in forging steels. About 0.017 to 0.024 kg of selenium per 0.9 metric ton of glass may be used in glass to neutralize the green tint of iron compounds. Large amounts produce pink and ruby glass. Selenium gives the only pure red color for signal lenses. Pigment for glass may

be in the form of the black powder, barium selenite, BaSeO_3 , or as sodium selenite, Na_2SeO_3 , and may be used with cadmium sulfide. Selenium is also used as an accelerator in rubber and to increase abrasion resistance.

In copper alloys, selenium improves machinability without hot shortness. Selenium copper is a free-cutting copper containing about 0.50% selenium. It machines easily, and the electric conductivity is nearly equal to that of pure copper. The tensile strength of the annealed selenium copper is about 207 MPa. Small amounts of selenium salts are added to lubricating oils to prevent oxidation and gumming.

Xerography is a dry printing method for the production of images by light or other rays. A thin layer of selenium is given a strong positive electrical charge and the design is projected on it, which discharges the selenium in proportion to the light intensity, producing a latent image. This image is developed by dusting with negatively charged particles that adhere to the plate where it was not struck by the projected light. Some further simple steps allow the image to be used as a master for many additional prints.

One of the oldest uses of selenium is in the glass and ceramic industries. The familiar ruby red that is commonly seen in glass is produced by cadmium selenide. The same cadmium-selenide reds find broad application in the field of ceramics and enamels.

Self-Absorption

In *optical emission spectroscopy*, reabsorption of a photon by the same species that emitted it. For example, light emitted by sodium atoms in the center of a flame may be reabsorbed by different sodium atoms near the outer portions of the flame.

Self-Acting Bearing

See *gas bearing* and *self-lubricating bearing*.

Self-Adjusting Arc Welding

This term usually refers to metal inert gas welding (MIG). It is so-called because the electrical characteristics of the equipment are such that the wire feed speed, the arc current, and the wire burn rate mutually interact to maintain a constant arc gap.

Self-Aligning Bearing

A *rolling-element bearing* with one spherical raceway that automatically provides compensation for shaft or housing deflection or misalignment. Compare with *aligning bearing*.

Self-Annealing Materials

Those materials that require no heat input to recrystallize when working at ambient temperatures, for example, tin and lead.

Self-Curing

See *self-vulcanizing*.

Self-Diffusion

Thermally activated movement of an atom to a new site in a crystal of its own species, as, for example, a copper atom within a crystal of copper.

Self-Extinguishing Resin

A resin formulation that will burn in the presence of a flame but will extinguish itself within a specified time after the flame is removed. The term is not universally accepted.

Self-Fluxing Alloys (Thermal Spraying)

Certain materials that “wet” the substrate and coalesce when heated to their melting point, without the addition of a fluxing agent.

Self-Hardening Steel

See preferred term *air-hardening steel*.

Self-Locking

Fastener bolts and similar threaded fasteners with antislackening features as described for self-locking nuts.

Self-Locking Nut

A nut with features that resist slackening resulting from in-service vibration and other inadvertent loads. Apart from the obvious risk of a joint completely parting if the nut is lost, even a limited reduction in preload raises the risk of fatigue failure. There are numerous locking features although they tend to fall into two categories. One general type, often termed *stiff nuts*, relies on some form of distortion of the nut thread to introduce a high level of friction against, and possibly indentation into, the mating thread. A second category has inserts of some resilient material, typically a hard plastic, set into the nut thread. With some types of locking features, it is good practice to discard the component after a single use as the locking effect can be much reduced on second tightening. Also see *lock nut*.

Self-Lubricating Bearing

(1) A bearing independent of external lubrication. These bearings may be sealed for life after packing with grease or may contain *self-lubricating material*. (2) A sintered product whose accessible pore volume is filled with a liquid lubricant that automatically produces a lubricating film on the bearing surface during running of the shaft. This is due to a pumping action of the shaft and frictional heat that lowers the viscosity of the oil. After completion of the running cycle, the oil is reabsorbed into the pore system of the bearing by capillary attraction. Porous self-lubricating bearings are divided into three groups: sintered bronze bearings, iron-based sintered bearings, and iron-bronze sintered bearings. The original of most widely used P/M bearing material is 90% Cu–10% Sn bronze, with or without the addition of graphite (1% fine natural graphite is often added to enhance fabrication, as well as to improve bearing properties). The 90% Cu–10% Sn bronze material is superior in bearing performance to the iron-based and iron-bronze compositions, which are lower in cost and used in less severe applications.

Self-Lubricating Material

Any solid material that shows low friction without application of a lubricant. Examples are graphite, molybdenum disulfide, and polytetrafluoroethylene. Taken in a broader context, the term can also refer to a composite (powder metallurgy) material into which a lubricous species has been incorporated. See also *self-lubricating bearing* and *solid lubricant*.

Self-Reversal

In optical emission spectroscopy, the extreme case of self-absorption. See also *self-absorption*.

Self-Skinning Foam

A urethane foam that produces a tough outer surface over a foam core upon curing.

Self-Tapping Screw

See *screw*.

Self-Vulcanizing

Pertaining to an adhesive that undergoes vulcanization without the application of heat. See also *vulcanization*.

Selvage

The woven-edge portion of a fabric used in reinforced plastics that is parallel to the warp.

Selvyt

A deep nap cloth used, with a suitable abrasive agent, for metallographic polishing.

S.E.M.

Scanning electron microscope. See *electron microscope*.

Semiautomatic Arc Welding

Arc welding with equipment that controls only the filler metal feed. The advance of the welding is manually controlled.

Semiautomatic Brazing

Brazing with equipment that controls only the brazing filler metal feed. The advance of the brazing is manually controlled.

Semiautomatic Plating

Plating in which prepared cathodes are mechanically conveyed through the plating baths, with intervening manual transfers.

Semiblind Joint

A weld joint in which one extremity of the joint is not visible.

Semiconductor

A solid crystalline material whose electrical conductivity is intermediate between that of a metal and an insulator, ranging from about 10^5 S to 10^{-7} S/m, and is usually strongly temperature dependent.

In a solid material, the electrons can exist only in certain bands of energy level that are separated by regions normally forbidden to electrons. Three general relationships between filled, unfilled, and forbidden bands can be considered. First, certain solids have some

S

allowed bands completely filled with electrons and others empty. If the forbidden regions between the allowed bands are large, the electrons cannot move from one band to the next and the material is an *insulator*. Second, in materials where bands are not completely filled or their energy levels overlap, the electrons can move freely between bands. The electrons moving in this manner are termed *conductivity electrons* and the material is a *metallic conductor*. Finally, in cases where the energy gap between a filled and an empty gap is small, then a small input of energy can cause an electron to jump the gap. Silicon is one example. At very low temperatures, the four valence electrons of each atom is associated in a strong covalent bond with another four electrons of an adjacent atom. As the temperature increases, that is, energy is added, electrons can move to another band leaving a site for an incoming electron and conductivity is achieved. Pure metals with this characteristic are termed *intrinsic semiconductors*. The effect can also be induced by adding particular impurity elements that assist an electron to bridge the forbidden gaps. The impurity elements are termed *dopants* and the alloyed materials are *extrinsic semiconductors*. The dopants can work in two ways. Silicon is a group IV element with four valence electrons, which, in its pure state, is an intrinsic semiconductor, as described earlier. However, if an atom of a group V element with five valence electrons is added to form a substitutional solid solution, one of the electrons is in excess of the number required for bonding so it takes up a position in the normally forbidden gap from where it is easily dislodged by a small energy input to contribute to conduction. Dopant elements contributing an excess electron are termed *donors*. In a similar manner, a group III element atom in solid solution will have only three valence electrons required for bonding with the four required by the adjacent silicon. This effectively produces a hole in the valence band that can accept electrons jumping from a silicon to silicon bond again contributing to conduction. Such elements are termed *acceptor dopants*. Conventionally, conductivity in semiconductors is considered on the basis of the movement of holes into which electrons can jump. The movement of a whole is regarded as a “positive” movement and hence the materials with an acceptor dopant providing holes are referred to as producing “p”-type semiconductors. Similarly, the movement of an electron is regarded as a negative movement of a hole and hence materials with a donor dopant are “n”-type semiconductors.

Semiconducting Materials

Semiconductors may be defined as materials that conduct electricity better than insulators, but not as well as metals. An enormous range of conductivities can meet this requirement. At room temperature, the conductivities characteristic of metals are on the order of 10^4 – $10^6 \Omega/\text{cm}$, while those of insulators range from 10^{-25} to $10^{-9} \Omega/\text{cm}$. The materials classed as semiconductors have conductivities that range from 10^{-9} to $10^4 \Omega/\text{cm}$. The conductivity of metals normally decreases with an increase of temperature, but semiconductors have the distinctive feature that in some range of temperature their conductivity increases rather than decreases with an increase of temperature.

Another criterion for a semiconductor is that the conduction process be primarily by electrons and not ionic, since the latter involves the transfer of appreciable mass as well as charge.

Materials used are ones that are capable of being partly conductors of electricity and partly insulators, and are used in rectifiers for changing alternating current to pulsating direct current, and in transistors for amplifying currents. They can also be used for the conversion of heat energy to electric energy, as in the solar battery. In an electric conductor, the outer rings of electrons of the atoms are free

to move, and provide a means of conduction. In a semiconductor, the outer electrons, or valence electrons, are normally stable, but, when a doping element that serves to raise or lower energy is incorporated, the application of a weak electric current will cause displacement of valence electrons in the material. Silicon and germanium, each with a single stable valence of four outer electrons, are the most commonly used semiconductors. Elements such as boron, with a lower energy level, but with electrons available for bonding and thus accepting electrons into the valence ring, are called *hypoelectronic elements*. Elements such as arsenic, which have more valence electrons that are needed for bonding and may give up an electron, are called *hyperelectronic elements*. Another class of elements, like cobalt, can either accept or donate an electron, and these are called *buffer atoms*. All of these types of elements constitute the doping elements for semiconductors.

In a nonconducting material, used as an electrical insulator, the energy required to break the valence bond is very high, but there is always a limit at which an insulator will break the bond and become a conductor with high current energy. The resistivity of a conductor rises with increasing temperature, but in a semiconductor the resistivity decreases with temperature rise, and the semiconductor becomes useless beyond its temperature limit. Germanium can be used as a semiconductor to about 93°C , silicon can be used to about 204°C , and silicon carbide can be used to about 343°C .

Extrinsic and Intrinsic Semiconductors

Metals for use as semiconductors must be of great purity, since even minute quantities of impurities would cause erratic action. The highly purified material is called an *intrinsic metal*, and the desired electron movement must come only from the doping element, or *extrinsic conductor*, that is introduced. The semiconductors are usually made of single crystals, and the positive and negative elements need be applied only to the surfaces of the crystal, but methods are also used to incorporate the doping element uniformly throughout the crystal.

The process of electron movement, although varying for different uses and in different intrinsic materials, can be stated in general terms. In the silicon semiconductor, the atoms of silicon with four outer valence electrons bind themselves together in pairs surrounded by eight electrons. When a doping element with three outer electrons, such as boron or indium, is added to the crystal, it tends to take an electron from one of the pairs, leaving a hole and setting up an imbalance. This forms the p-type semiconductor. When an element with five outer electrons, such as antimony or bismuth, is added to the crystal, it gives off electrons, setting up a conductive band, which is the n-type semiconductor. Fusing together the two types forms a p–n junction, and a negative voltage applied to the p side attracts the electrons of the three-valence atoms away from the junction so that the crystal resists electronic flow. If the voltage is applied to the n side, it pushes electrons across the junction and the electrons flow. This is a diode, or rectifier, for rectifying alternating current into pulsating direct current. When the crystal wafers are assembled in three layers, p–n–p or n–p–n, a weak voltage applied to the middle wafer increases the flow of electrons across the whole unit. This is a transistor. Germanium and silicon are bipolar, but silicon carbide is unipolar and does not need a third voltage to accelerate the electrons.

Semiconductors can be used for rectifying or amplifying, or they can be used to modulate or limit the current. By the application of heat to ionize the atoms and cause movement, they can also be used to generate electric current; or in reverse, by the application of a current they can be used to generate heat or remove heat for heating

or cooling purposes and air conditioning, heating, and refrigeration. But for uses other than rectifying or altering electric current, the materials are usually designated by other names and not called semiconductors. Varistors are materials, such as silicon carbide, whose resistance is a function of the applied voltage. They are used for such applications as frequency multiplication and voltage stabilization. Thermistors are thermally sensitive materials. Their resistance decreases as the temperature increases, which can be measured as close as 0.001°C , and they are used for controlling temperature or to control liquid level, flow, and other functions affected by rate of heat transfer. They are also used for the production or the removal of heat and air conditioning, and may then be called thermoelectric metals.

Hall Effect

Whether a given sample of semiconductor material is n- or p-type can be determined by observing the Hall effect. If an electric current is caused to flow through a sample of semiconductor material and a magnetic field is applied in a direction perpendicular to the current, the charge carriers are crowded to one side of the sample, giving rise to an electric field perpendicular to both the current and the magnetic field. This development of a transverse electric field is known as the Hall effect. The field is directed to one or the opposite direction depending on the sign of the charge of the carrier.

The magnitude of the Hall effect gives an estimate of the carrier concentration. The ratio of the transverse electric field strength to the product of the current and the magnetic field strength is called the Hall coefficient, and its magnitude is inversely proportional to the carrier concentration. The coefficient of proportionality involves a factor that depends on the energy distribution of the carriers and the way in which the carriers are scattered in their motion. However, the value of this factor normally does not differ from unity by more than a factor of 2. The situation is more complicated when more than one type of carrier is important for the conduction. The Hall coefficient then depends on the concentration of the various carriers and their relative mobilities.

The product of the Hall coefficient and conductivity is proportional to the mobility of the carriers when one type of carrier is dominant. The proportionality involves the same factor that is contained in the relationship between the Hall coefficient and the carrier concentration. The value obtained by taking this factor to be unity is referred to as the Hall mobility.

Types

Although some of the chemical elements are semiconductors, most semiconductors are chemical compounds. Compound semiconductors can be simple compounds, such as compounds formed from elements of the III-V, V-VI, II-IV, II-VI, I-VI, II-V, II-VI groups of the periodic table, as well as alloys of these compounds, ternary compounds, complicated oxides, and even organic complexes.

For organic semiconductors, it is generally true that the larger the molecule, the higher the conductivity. Inclusion of atoms other than carbon, hydrogen, and oxygen in the molecule often appears to increase the conductivity. The phthalocyanine molecule, which is much like the active center of several biologically active compounds, for example, chlorophyll, can accommodate a metallic atom in its center.

An organic semiconductor may be either n-type or p-type. For example, among the organic dyes, the cationic dyes appear to be n-type semiconductors and the anionic dyes p-type.

Magnetic ferrites are usually polycrystalline ceramics, composed of mixed semiconductor and oxides, and possess useful magnetic properties combined with high electrical resistivities.

The magnetically soft ferrites have the general form MFe_2O_4 , where M represents one or more of the following divalent metals: copper, magnesium, manganese, nickel, iron, and zinc. The crystallites have the cubic structure of the spinel system.

Fabrication

Although some electronic devices require extremely small semiconductor elements, others require large masses of material. For example, some diodes and thermistors have volumes, exclusive of the lead wires, of less than 1 ten-millionth of a cubic inch, while some silicon domes require as much as a 1000 m^3 of material, and xerographic and luminescent panels cover many square centimeters. Semiconductors are prepared in the form of single crystals (as large as several millimeters in diameter and several centimeters in length), polycrystalline ingots, thin films, or sintered ceramic shapes. Semiconductors are generally brittle materials and some make excellent abrasives. However, at higher temperatures (near their melting points) they can be deformed elastically in a manner analogous to engineering metals at room temperature.

Single crystals and polycrystalline ingots can be cut into the desired shapes by using diamond or other appropriate abrasive wheels or by using ultrasonic cutting tools and a boron carbide abrasive. A continuous wire and an abrasive slurry are sometimes used for cutting semiconductors. Mapping and etching are commonly used for preparing small semiconductor elements of the desired shape and surface condition. Large-area selenium xerographic plates are prepared by vacuum evaporation, whereas ceramic molding and sintering techniques are used in the preparation of ferrites and some luminescent materials.

Single crystals are grown by the horizontal Bridgman, the vertical Bridgman, Czochralski, floating-zone, and vapor-phase deposition techniques. The impurities may be added to the starting materials or to the melt during growth. Controlled regions of impurities are created by diffusion, alloying, or vapor-phase deposition to form epitaxial layers on a single-crystal substrate.

Some semiconductor elements are formed by use of a semiconductor powder in an appropriate binder. In the manufacture of magnetic ferrites, the oxides are mixed in required proportions and milled to obtain a fine particle size. The powder is then partially sintered in a pre firing kiln, and subsequently crushed, milled, and granulated before being pressed or extruded into the required shape. The main firing cycle takes place at temperatures around 1250°C in a controlled atmosphere. As a result, the parts are sintered into a dense, homogeneous ceramic. During sintering, the parts shrink some 20% M linear dimensions.

Applications

The technology and practical importance of semiconductor devices have been growing steadily in the past decade. The major applications of semiconductors can be divided into 10 categories: diodes and transistors, luminescent devices, ferrites, special resistors, photovoltaic cells, infrared lenses and domes, thermoelectric devices, piezoelectric devices, xerography, and electron emission.

Indium antimonide, InSb , has a cubic crystal structure, and it is used for infrared detectors and for amplifiers in galvanomagnetic devices. Indium arsenide, InAs , also has a very high electron mobility, and is used in thermistors for heat-current conversion. It can be used to 816°C . Some materials can be used only for relatively low temperatures. Copper oxide and pure selenium have been much used in current rectifiers, but they are useful only at moderate temperatures, and they have the disadvantage of requiring much space. Indium phosphide, InP , has a mobility higher than that of germanium,

S

and can be used in transistors above 316°C. Aluminum antimonide, AlSb, can be used at temperatures to 538°C. In lead selenide, PbSe, the mobility of the charge-carrying electrons decreases with rise in temperature, increasing resistivity. It is used in thermistors.

Bismuth telluride, Bi₂Te₃, maintains its operating properties between -46°C and 204°C, which is the most useful range for both heating and refrigeration. When doped as a p-type conductor, it has a temperature difference of 601°C and an efficiency of 5.8%. When doped as an n-type conductor, the temperature difference is lower, 232°C, but the efficiency within this range is more than doubled. Lead telluride, PbTe, has a higher efficiency, 13.5%, and temperature difference of 582°C, but it is not usable below 177°C, and is employed for conversion of the waste heat atomic reactors at about 371°C.

Gallium arsenide has high electron mobility, and can be used as a semiconductor. Cadmium sulfide, CdS, is thus deposited as a semiconductor film for photovoltaic cells, or solar batteries, with film thickness of about 2 μm. When radioactive isotopes, instead of solar rays, are added to provide the activating agent, the unit is called an atomic battery, and the large area of transparent backing for the semiconductor is not needed.

Manganese telluride, MnTe, with a temperature difference of 982°C, has also been used as a semiconductor. Many other materials can be used, as semiconductors with temperature differences at different gradients can be joined in series electrically to obtain a wider gradient, but the materials must have no diffusion at the junction.

Cesium sulfide, CsS, has good stability and thermoelectric properties at temperatures to 1093°C, and has a high temperature difference, 1110°C. It can thus be used as a high-stage unit in conversion devices. High conversion efficiency is necessary for transducers, while a high dielectric constant is desirable for capacitors. Low thermal conductivity makes it easier to maintain the temperature gradient, but for some uses high thermal conductivity is desirable. Silver-antimony-telluride, AgSbTe₂, has a high energy-conversion efficiency for converting heat to electric current, and it has a very low thermal conductivity, about 1% that of germanium.

The semiconductor-type intermetals are also used in magnetic devices, since the ferroelectric phenomenon of heat conversion is the electrical analog of ferromagnetism. Chromium-manganese-antimonide is nonmagnetic below about 250°C and magnetic above the temperature. Various compounds have different critical temperatures. Below the critical temperature, the distance between the atoms is less than that which determines the lineup of magnetic forces, but with increased temperature the atomic distance becomes greater and the forces swing into a magnetic pattern.

Organic semiconductors fall into two major classes: well-defined substances, such as molecular crystals and crystalline complexes, and isotactic and syndiotactic polymers; and disordered materials, such as atactic polymers and pyrolytic materials. Few of these materials have yet found commercial application.

Amorphous silicon containing hydrogen is promising for use in solar cells because of its low cost and suitable electrical and optical properties.

Semicrystalline

In plastics, materials that exhibit localized crystallinity. See also *crystalline plastic*.

Semifinisher

An impression in a series of forging dies that only approximates the finished dimension of the forging. Semifinishers are often used

to extend die life or the finishing impression, to ensure proper control of grain flow during forging, and to assist in obtaining desired tolerances.

Semifinishing

Preliminary operations performed prior to finishing.

Semiguided Bend

The bend obtained by applying a force directly to the specimen than the portion that is to be bent. The specimen is either held at one end and forced around a pin or rounded edge, or is supported near the ends and then by a force applied on the side of the specimen opposite the supports and midway between them. In some instances, the bend is started in this manner and finished in the manner of a *free bend*.

Semikilled Steel

Steel that is incompletely deoxidized and contains sufficient dissolved oxygen to react with the carbon to form carbon monoxide and thus offset solidification shrinkage. The voids filled with carbon dioxide are closed during subsequent hot working. See the term *capped steel*.

Semimetal

An element having many but not all of the characteristics of a metal. Also termed a metalloid.

Semipermanent Mold

A *permanent mold* in which fresh sand cores are used repeatedly.

Semipermeable Membrane

A membrane that is permeable to the solvent but impervious to the solute.

Semipositive Mold

A mold for forming plastics that combines the capabilities of a *flash mold* and *positive mold*. As the two halves of a semipositive mold begin to close, the mold acts much like a flash mold, because the excess material is allowed to escape around the loose-fitting plunger and cavity. As the plunger telescopes further into the cavity, the mold becomes a positive mold with very little clearance, and full pressure is exerted on the material, producing a part of maximum density. This type of mold uses to advantage the free flow of material in a flash mold and the capability of producing dense parts and the positive mold.

Semirigid Plastic

For purposes of general classification, a plastic that has a modulus of elasticity and flexure or in tension between 70 and 690 MPa (10 and 100 ksi) at 23°C and 50% relative humidity.

Semisolid Metal Forming

A two-step casting/forging process in which a billet is cast in a mold equipped with a mixture that continuously stirs the thixotropic melt,

thereby breaking up the dendritic structure of the casting into a fine-grained spherical structure. After cooling, the billet is stored for subsequent use. Later, a slug from the billet is cut, heated to the semisolid state, and forged in a die. Normally the cast billet is forged when 30%–40% is in the liquid state. See also *rheocasting*.

Semi Steel

Low carbon cast iron having graphite flakes small in size and quantity and well distributed and hence having relatively good ductility compared with normal gray cast iron. It is usually made by melting scrap steel with the pig iron.

Sendzimir Mill

A type of *cluster mill* with small-diameter work rolls and larger-diameter backup rolls, backed up by bearings on a shaft mounted eccentrically so that it can be rotated to increase the pressure between the bearing and the backup rolls. Used to roll precision and very thin sheet and strip.

Sensitive Tint Plate

A gypsum plate used in conjunction with polarizing filters in an *optical microscope* to provide very sensitive detection of birefringence and double refraction.

Sensitivity

- (1) The capability of a method or instrument to discriminate between samples having different concentrations or amounts of the analyte.
- (2) The smallest difference in values that can be detected reliably with a given measuring instrument.

Sensitization

In austenitic stainless steels, the precipitation of chromium carbides, usually at grain boundaries, on exposure to temperatures of about 540°C–845°C, leaving the grain boundaries depleted of chromium and therefore susceptible to preferential attack by a corroding medium. Welding is the most common cause of sensitization. Weld decay (sensitization) caused by carbide precipitation in the weld heat-affected zone leads to *intergranular corrosion*.

Sensitizing Compounds

Supersensitizing compounds are metal salts in an aqueous or organic solution, which form an invisible film on the surface of glass and other ceramic surfaces. This film is not completely understood but is believed to be an ionizing or electronic effect that serves to initiate and hastened surface treatments such as silvering and plating. Supersensitizing refers to a second step involving the use of noble metal compounds, which further enhances the reduction properties of the metals about to be formed on the glass or ceramic surface.

Sensitizing compounds include aluminum compounds (basic aluminum acetate, aluminum chloride, aluminum formoacetate, aluminum nitrate), barium salts, boron trichloride, cadmium compounds, iron sulfate, tin chloride, titanium sulfate, and triethanolamine titanate.

Supersensitizing compounds include gold chloride, iridium salts, osmium compounds, palladium chloride, silver nitrate, and silver oxide.

Sensitizing Heat Treatment

A heat treatment, whether accidental, intentional, or incidental (as during welding), that causes precipitation of constituents at grain boundaries, often causing the alloy to become susceptible to *intergranular corrosion* or *intergranular stress-corrosion cracking*. See also *sensitization*.

Sensor

Any detection device, with or without a measuring capability.

Separate-Application Adhesive

An adhesive consisting of two parts, one part being applied to one adherend and the other part to the other adherend and the tube being brought together to form a joint.

Separator

In rolling-element bearings, the part of a cage that lies between the rolling elements. This term is sometimes used as a synonym for *cage*. See the term *rolling-element bearing*.

Separator (Composites)

In processing of composites, a permeable layer that allows volatiles and air to escape from the laminate and excess resin to be bled from the laminate into the bleeder plies during cure. Porous Teflon-coated fiberglass is an example. Often placed between lay-up and bleeder to facilitate bleeder systems removal from laminate after cure. See also *bleeder* and *lay-up*.

Sequence Timer

In resistance welding, a device used for controlling the sequence and duration of any or all of the elements of a complete welding cycle except *heat time* or *weld time*.

Sequence Weld Timer

Same as *sequence timer* except that either *weld time* or *heat time*, or both, are also controlled.

Sequestering Agent

A material that combines with metallic ions to form water-soluble complex compounds.

Serial Sectioning

A metallographic technique in which an identified area on a section surface is observed repeatedly after successive layers of known thickness have been removed from the surface. It is used to construct a 3D morphology of structural features. See also *sectioning*.

Series Submerged Arc Welding

A submerged arc welding process variation in which electric current is established between two (consumable) electrodes that meet

S

just above the surface of the work. The work is not in the electrical circuit. See also *submerged arc welding*.

Series Welding

Resistance welding in which two or more spot, seam, or projection welds are made simultaneously by a single welding transformer with three or more electrodes forming a series circuit.

Serpentine

A mineral of theoretical formula $3\text{MgO} \cdot \text{SiO}_2 \cdot 2\text{H}_2\text{O}$, containing 43% magnesium oxide. It is used for building trim and for making ornaments and novelties. The chips are employed in terrazzo and for roofing granules. Actually, the stone rarely approaches the theoretical formula and usually contains 2%–8% iron oxide with much silica and aluminum. It has an asbestos-like structure. The attractively colored and veined serpentine of Vermont is marketed under the name of *verde antique marble*. The massive verde antique of Pennsylvania is used with dolomite in refractories. *Antigorite* is a form of serpentine found in California, which has a platy rather than a fibrous structure. The serpentine of Columbus County, Georgia, contains 36%–38% MgO and 2–5 chrome ore. It is used as a source of magnesia.

Sessile Dislocation

A dislocation formed by a plane of vacancies surrounded by normal lattice. This type of dislocation cannot move.

Set

(1) The shape of the solidifying surface of a metal, especially copper, with respect to concavity or convexity. May also be called pitch. (2) Deformation. (3) A substantial chisel for cutting metal.

Set (Polymerization)

To convert an adhesive into a fixed or hardened state by chemical or physical action, such as condensation, polymerization, oxidation, vulcanization, gelation, hydration, or evaporation of volatile constituents. See also *cure*.

Set Copper

An intermediate copper product containing about 3.5% cuprous oxide, obtained at the end of the oxidizing portion of the fire-refining cycle.

Set, Permanent

See *permanent set*.

Setting Temperature

The temperature to which an adhesive or an assembly is subjected to set the adhesive. The temperature attained by the adhesive in the process of setting (adhesive setting temperature) may differ from the temperature of the atmosphere surrounding the assembly (assembly setting temperature). See also *curing temperature* and *drying temperature*.

Setting Time

The period of time during which an adhesively bonded assembly is subjected to heat or pressure, or both, to set the adhesive. See also *drying time* and *joint-conditioning time*.

Settling

(1) Separation of solids from suspension in a fluid of lower density, solely by gravitational effects. (2) A process for removing iron from liquid magnesium alloys by holding the melt at a low temperature after manganese has been added to it.

Set Up

To harden, as in the curing of a polymer resin.

Severe Wear

A form of wear characterized by removal of material in relatively large fragments. Severe wear is an imprecise term, frequently used in research, and contrasted with *mild wear*. In fact, the phenomena studied usually involve the transition from mild to severe wear and the factors that influence that transition. With metals, the fragments are usually predominantly metallic rather than oxidic. Severe wear is frequently associated with heavy loads and/or adhesive contact.

Severity of Quench

Ability of quenching medium to extract heat from a hot steel workpiece; expressed in terms of the *Grossman number* (*H*).

S-Glass

A magnesium aluminosilicate composition that is especially designed to provide very high tensile strength glass filaments. S-glass and S-2 glass fibers have the same glass composition but different finishes (coatings), S-glass is made to more demanding specifications, and S-2 is considered a commercial grade. See the term *fiberglass*.

Shadow Angle

In shadowing of replicas, the angle between the line of motion of the evaporated atoms and the surface being shadowed. See also *replica* and *shadowing*.

Shadow Cast Replica

A replica that has been shadowed. See also *replica* and *shadowing*.

Shadowing

Directional deposition of carbon or a metallic film on a plastic replica so as to highlight features to be analyzed by transmission electron microscopy. Most often used to provide maximum detail and resolution of the features of fracture surfaces. The process is carried out in a vacuum chamber in which a suitable metal is evaporated and projected to an acute angle onto the replica surface to exaggerate topographical irregularities. See also *metal shadowing*, *oblique evaporation shadowing*, and *shadow angle*.

Shadow Mask (Thermal Spraying)

A thermal spraying process variation in which an area is partially shielded during the thermal spraying operation, thus permitting some overspray to produce a feathering at the coating edge.

Shadow Microscope

An electron microscope that forms a shadow image of an object using electrons emanating from a point source located close to the object.

Shaft Furnace

A vertical cylindrical furnace packed nearly to the top with the charge. The materials are continuously fed in the top to react as they progress down to be extracted at the base. See *blast furnace*.

Shaft Run-Out

Twice the distance that the center of a shaft is displaced from the axis of rotation; that is, twice the eccentricity.

Shakeout

Removal of castings from a sand mold. See also *knockout*.

Shaker-Hearth Furnace

A continuous type furnace that uses a reciprocating shaker motion to move the parts along the hearth.

Shale

A rock formed by deposition of colloidal particles of clay and mud, and consolidated by pressure. It is fine-grained and has a laminated structure, usually containing much sand colored by metal oxides. Unlike sandstones, shales are not usually porous; most are hard, slatelike rocks. Slate is a form of shale that has been subjected to intense pressure. Some shales are calcareous or dolomitic and are used with limestone in making portland cement. These are called *marlstone*. *Oil shale* is a hard shale with veins of greasy solid known as *kerogen*, which is oil mixed with organic matter. *Crude shale oil* is a black, viscous liquid containing up to 2% nitrogen and a high sulfur content. But when oil shale is heated above 399°C, the kerogen is cracked into gases condensable to oils, gases, and coke. Some shales also yield resins and waxes and others contain small amounts of uranium, vanadium, and molybdenum. The regular commercial by-products of *Swedish shale oil* recovery are sulfur, fuel gas, ammonium sulfate, tar, and lime. Shales contain abrasive particles of platelike shape. The term is applied particularly to diamond abrasives.

Shank

(1) The portion of a die or tool by which it is held in position in a forging unit or press. (2) The handle for carrying a small ladle or crucible. (3) The main body of a lathe tool. If the tool is an inserted type, the shank is the portion that supports the insert. (4) The plain shaft that carries the active end of a component, for example, the unthreaded central length of a bolt or the plain end of a drill bit.

Shank-Type Cutter

A cutter having a straight or tapered shank to fit into a machine-tool spindle or adapter.

Shape Accuracy

For an elastic slab loaded in compression, the ratio of the loaded area to the force-free area.

Shape Memory Alloys

These are a group of metallic materials that can return to some previously defined shape or size when subjected to the appropriate thermal procedure. That is, shape memory alloys (SMA) can be plastically deformed at some relatively low temperature and, upon exposure to some higher temperature, will return to their original shape. Materials that exhibit shape memory only upon heating are said to have a one-way shape memory, whereas those that also undergo a change in shape upon recooling have a two-way memory. Typical materials that exhibit the shape memory effect include a number of copper alloy systems and the alloys of gold-cadmium, nickel-aluminum, and iron-platinum.

A shape memory alloy may be further defined as one that yields a thermoelastic martensite, that is, a martensite phase that is crystallographically reversible. In this case, the alloy undergoes a martensitic transformation of a type that allows the alloy to be deformed by a twinning mechanism below the transformation temperature. A twinning mechanism is a herringbone structure exhibited by martensite during transformation. The deformation is then reversed when the twinned structure reverts upon heating to the parent phase.

Transformation Characteristics

The martensite transformation that occurs in shape memory alloys yields a thermoelastic martensite and develops from a high-temperature austenite phase with long-range order. The martensite typically occurs as alternately sheared platelets, which are seen as a herringbone structure when viewed metallographically. The transformation, although a first-order phase change, does not occur at a single temperature but over a range of temperatures that is characteristic for each alloy system.

There is a standard method of characterizing the transformation and naming each point in the cycle. Most of the transformation occurs over a relatively narrow temperature range, although the beginning and end of the transformation during heating and cooling actually extends over a much larger temperature range. The transformation also exhibits hysteresis in that the transformation on heating and cooling does not overlap. This transformation hysteresis varies with the alloy system.

Thermomechanical Behavior and Alloy Properties

The mechanical properties of shape memory alloys vary greatly over the temperature range spanning their transformation. The only two alloy systems that have achieved any level of commercial exploitation are the nickel-titanium alloys and the copper-base alloys. Properties of the two systems are quite different. The nickel-titanium alloys have greater shape memory strain, tend to be much more thermally stable, have excellent corrosion resistance compared to the copper-base alloys, and have higher ductility. The copper-base alloys are much less expensive, can be melted and extruded in air

S

with ease, and have a wider range of potential transformation temperatures. The two alloy systems thus have advantages and disadvantages that must be considered in a particular application.

Materials

The most common shape memory alloy material is *nitinol*, an acronym for Ni-Ti-NOL (Naval Ordinance Laboratory). As suggested by the name, the material consists of approximately equal parts of nickel and titanium and was originally developed by the Naval Ordinance Laboratory.

Two different phases, martensite and austenite, are typically associated with the crystalline structure of shape memory alloys. The austenite phase is a highly ordered phase that occurs above a certain transition temperature. In this phase, the crystalline bonds must be at right angles with one another. The martensite phase occurs below the transition temperature, and right angle bonds are not required, where a twinned phase occurs. Strain is required to achieve a particular alignment, since the martensite phase is not in an ordered state.

The term *shape memory* is derived from the fact that a shape memory alloy can recover its original shape when heated above a certain transition temperature. Before a shape memory alloy such as nitinol can present shape memory behavior, it must first be trained. The shape memory alloy is annealed while it is constrained in the shape that it is to memorize. From a microscopic view, this corresponds to the austenite phase. For the nitinol wire, the annealing process corresponds to a contraction in the length of the wire. After annealing, the material is said to have a one-way shape memory.

The nitinol recovers its memorized shape when heated above the transition temperature and will remain in that shape upon cooling. For the shape memory alloy to return to its initial shape, an external force must be applied to deform it. The two-way shape memory corresponds to a martensite phase to austenite phase by heating (shape recovery) followed by a mechanically produced deformation of the material upon cooling.

Applications

The manufacturing and the technology associated with both of the two commercial classes of shape memory alloys are quite different as are the performance characteristics. Therefore, in applications where a highly reliable product with a long fatigue life is desired, the nickel–titanium alloys are the exclusive materials of choice. Typical applications of this kind include electric switches and actuators. However, if high-performance is not mandated and cost considerations are important, then the use of copper–zinc–aluminum shape memory alloys can be recommended. Typical applications of this kind include safety devices such as temperature fuses and fire alarms.

Heating a shape memory alloy product to a temperature above some critical temperature is not recommended. The critical temperature for nickel–titanium is approximately 250°C, and for copper–zinc–aluminum approximately 90°C. Extended exposure to thermal environments above these critical temperatures results in an impaired memory function regardless of the magnitude of the load.

Another technical consideration in the practical application of shape memory alloys pertains to fastening or joining these materials to conventional materials. This is a significant issue because shape memory alloys undergo expansions and contractions not encountered in traditional materials. Therefore, if shape memory alloys are

welded or soldered to other materials, they can easily fail at the joint when subjected to repeated loading. Alloys of nickel–titanium and copper–zinc–aluminum can also be brazed by using silver filler metals; however, the brazed region can fail because of cyclic loading. It is therefore desirable to devise some other mechanism for joining shape memory alloys to traditional materials. Shape memory alloys cannot be plated or painted for similar reasons.

Free Recovery

In this case, a component fabricated from a shape memory alloy is deformed while martensitic, and the only function required of the shape memory is that the component return to its previous shape upon heating. A prime application is the blood-clot filter in which a nickel–titanium wire is shaped to anchor itself in a vein and catch passing clots. The part is chilled so it can be collapsed and inserted into the vein; then body heat is sufficient to return the part to its functional shape.

Constrained Recovery

The most successful example of this type of product is undoubtedly a hydraulic coupling. These studies are manufactured as cylindrical sleeves slightly smaller than the metal tubing that they are to join. Their diameters are then expanded while martensitic and, upon warming to austenite, they shrink in diameter and strongly hold the tube ends. The tubes prevent the coupling from fully recovering its manufactured shape, and the stresses created as the coupling attempts to do so are great enough to create a joint that, in many ways, is superior to a weld.

Force Actuators

In some applications, the shape memory component is designed to exert force over a considerable range of motion, often for many cycles. Such an application is the circuit-board edge connector. In this electrical connector system, the shape memory alloy component is used to force open a spring when the connector is heated. This allows force-free insertion or withdrawal of a circuit board in the connector. Upon cooling, the nickel–titanium actuator becomes weaker, and the spring easily deforms the actuator while it closes tightly on the circuit board and forms the connections.

An example based on the same principle is a fire safety valve, which incorporates a copper–zinc–aluminum actuator designed to shut off toxic or flammable gas flow when fire occurs.

Other Applications

A number of applications are based on the pseudoelastic (or superelastic) property of shape memory alloys. Some eyeglass frames use superelastic nickel–titanium alloy to absorb large deformations without damage. Guide wires for steering catheters into vessels in the body have been developed using wire fashioned of nickel–titanium alloy, which resists permanent deformation if bent severely. Arch wires for orthodontic correction also use this alloy.

Shape memory alloys have found application in the field of robotics. The two main types of actuators for robots using these alloys are biased and differential. Biasing uses a coil spring to generate the bias force that opposes the unidirectional force of the shape memory alloy. In the differential type, the spring is replaced with another shape memory alloy, and the opposing forces control the actuation. A microrobot was developed with five degrees of freedom corresponding to the capabilities of the human fingers, wrist, elbow, and shoulder. The variety of robotic maneuvers and operations are coordinated by activating the nickel–titanium coils in the fingers and

wrist in addition to contraction and expansion of straight nickel–titanium wires in elbow and shoulders. Digital control techniques in which a current is modulated with pulse-width modulation are employed in all of the components to control their spatial positions and speeds of operation.

In medical applications, in addition to mechanical characteristics, highly reliable biological and chemical characteristics are very important. The material must not be vulnerable to degradation, decomposition, dissolution, or corrosion in the organism, and must be biocompatible.

Nickel–titanium shape memory alloys have also been employed in artificial hip joints. These alloys have also been used for bone plates, for marrow pins for healing bone fractures, and for connecting broken bones.

Shape Memory Effect (S.M.E.)

An effect, observed in some alloy systems, which is associated with a reversible and progressive transformation to martensite as temperature falls. The unusual characteristic is that if the material is deformed (within limits) while in one phase, it will, on changing temperature to the other phase, refer to the original shape.

Shaping

Producing flat surfaces using single-point tools. The work is held in a vise or fixture, or is clamped directly to the table. The ram supporting the tool is reciprocated in a linear motion past the work.

1. Form shaping: Shaping with a tool ground to provide a specified shape.
2. Contour shaping: Shaping of an irregular surface, usually with the aid of a tracing mechanism.
3. Internal shaping: Shaping of internal arms such as keyways and guides.

Shark Leather

A durable, nonscuffing leather used for bookbindings, handbags, and fancy shoes, made from the skin of sharks. The shark is the largest of the true fishes, but has a skin unlike fishskin. When tanned, the surface is hard, the epidermis thicker than cowhide, and the long fibers lie in a cross-weave. The shark is split on the back instead of the belly, as in cowhides, and the skins measure from 3 to 20 ft² (0.3–2 m²). The hard denticle, called the *shagreen*, is usually removed, after which the leather is pliable but firm, the exposed grain not pulling out. *Shagreen leather* is a hard, strong leather with the grain side covered with globular granules made to imitate the sharkskin. Eastern shark leather has a deep grain with beautiful markings. *Pearl sharkskin* is from the Japanese ray. It is used for trim on pocketbooks. *Morocco leather* is from a small shark of the Mediterranean, but the name is also applied to a vegetable-tanned Spanish goatskin on which a pebbly grain is worked up by hand boarding. It is now made from ordinary goatskin by embossing.

Most of the sharkskin is now a by-product of the catch for oil, which is used for medicinal purposes. The shark liver is about one-fourth the total weight of the animal, and *shark-liver oil* is 30 times higher in vitamin A than cod-liver oil. The oil is also used for soap, lubricating, and heat-treating oil, though normally it is too expensive for these purposes.

Shark's Teeth

In ceramics and glasses, a striation consisting of dagger-like step fractures starting at the scored edge and extending to or nearly to the compression edge.

Sharp-Notch Strength (σ_s)

The notch tensile strength measured using specimens with very small notch root radii (approaching the limit for machining capability); values of sharp-notch strength usually depend on notch root radius.

Shatter Cracking

Low ductility cracking, usually subsurface, by various mechanisms including brittle fracture and hydrogen embrittlement. It is also termed as fisheyes or flakes. See *flake* (metals).

Shaving

(1) As a finishing operation, the accurate removal of a thin layer of a work surface by straight line motion between a cutter and the surface. (2) Trimming parts such as stampings, forgings, and tubes to remove uneven sheared edges or to improve accuracy.

Shaw (Osborn-Shaw) Process

See *ceramic molding*.

Shear

(1) The type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact. (2) A machine or tool for cutting metal and other material by the closing motion of two sharp, closely adjoining edges; for example, *squaring shear* and *circular shear*. (3) An inclination between two cutting edges, such as between two straight knife blades or between the punch cutting edge and the die-cutting edge, so that a reduced area will be cut each time. This lessens the necessary force but increases the required length of the working stroke. This method is referred to as angular shear. (4) The act of cutting by shearing dies or blades, as in shearing lines. (5) The cutting action where a pair of blades or similar abutting faces slide across each other cutting the entrapped material as with scissors. Shear strength, in this context, refers to the capacity to resist this form of loading. (6) The deformation mechanism in which layers of atoms on the crystal lattice slide across one another like a pack of playing cards. The layers involved, termed the shear planes, are usually those at an angle of 45° to the principle stress. Shear strength in this context refers to the stress necessary to induce permanent deformation by such a mechanism.

Shear Angle

The angle that the *shear plane*, in metal cutting, makes with the work surface.

Shear Bands

(1) Bands of very high shear strain that are observed during rolling of sheet metal. During rolling, these form at approximately $\pm 35^\circ$

S

to the rolling plane, parallel to the transverse direction. They are independent of grain orientation and at high strain rates traverse the entire thickness of the rolled sheet. (2) Highly localized deformation zones in metals that are observed at very high strain rates, such as those produced by high velocity (100–3,600 m/s, or 330–11,800 ft/s) projectile impacts or explosive rupture. During high-strain-rate shear, also known as adiabatic shear, the bulk of the plastic deformation is concentrated in narrow bands within the relatively undeformed matrix. The shear bands are believed to occur along slip planes and the local strain rate within the adiabatic shear bands can exceed 10^6 s^{-1} .

Shear Edge

The cut off edge of a mold.

Shear Fracture

A mode of fracture in crystalline materials resulting from translation along slip planes that are preferentially oriented in the direction of the shearing stress.

Shear Hackle

A *hackle* in ceramics and glasses generated by interaction of a shear component with the principal tension under which the crack is running.

Shear Ledges

Steps between areas of crystalline fracture on a brittle fracture surface. They are normally aligned along the line of crack propagation and hence pointed to the origin. See *radial marks*.

Shear Lip

(1) A narrow, slanting ridge along the edge of a fracture surface. The term sometimes also denotes a narrow, often crescent-shaped, fibrous region at the edge of a fracture that is otherwise of the cleavage type, even though this fibrous region is in the same plane as the rest of the fracture surface. (2) An area, at the edge of a flat fracture surface, where the plane of fracture is at about 45° to the direction of loading. It occurs by ductile shear at the final stage of crack propagation leaving, usually, a sharp fracture edge. See *shear* (5).

Shear Modulus (G)

The ratio of shear stress to the corresponding shear strain for shear stresses below the proportional limit of the material. Values of shear modulus are usually determined by torsion testing. Also known as modulus of rigidity. Same as *bulk modulus*.

Shear Plane

A confined zone along which shear takes place in metal cutting. It extends from the cutting edge to the work surface. See *shear* (6).

Shear Rate

With regard to viscous fluids, the relative rate of flow or movement.

Shear Stability

The ability of a lubricant to withstand shearing without degradation. See also *penetration* (of a grease).

Shear Strain

The tangent of the angular change, caused by a force between two lines originally perpendicular to each other through a point in a body. Also called *angular strain*.

Shear Strength

The maximum shear stress that a material is capable of sustaining. Shear strength is calculated from the maximum load during a shear or torsion test and is based on the original cross-sectional area of the specimen. See *shear, definitions* (5) and (6).

Shear Stress

(1) The stress component tangential to the plane on which the forces act. (2) A stress that exists when parallel planes in metal crystals slide across each other.

Shear Stress (Plastics)

The stress developing in a polymer melt when the layers in a cross section are gliding along each other or along the wall of the channel (in laminar flow). Shear stress is equal to force divided by the area sheared, yielding pounds per square inch.

Shearing

The parting of material that results when one blade forces the material past an opposing blade. See also *shear*.

Shear Thickening

An increase in viscosity of non-Newtonian fluids (e.g., polymers and their solutions, slurries, and suspensions) with an increase in shear stress or time. See also *shear thinning*.

Shear Thinning

A decrease in viscosity of non-Newtonian fluids with an increase in shear stress or time. The decrease in viscosity may be temporary or permanent. The latter happens when the shear stress is sufficiently large to rupture a chemical bond, so that the sheared liquid has a lower viscosity than it had prior to shearing. See also *shear thickening*.

Sheared-Off

This term is used loosely with respect to virtually any failure of a bolt or similar fastener. It is probably best limited to those cases where the bolt has been cut by a shearing action of one bolted surface sliding across the other.

Sheath

(1) The material, usually an extruded plastic or elastomer applied outermost to a wire or cable. Also called a jacket. (2) A sheet metal or

glass covering of a sintered billet to protect it from oxidation or other environmental contamination during hot working. See also *can*.

Shed

A feature intended to shed, that is, discard, unwanted deposits.

Sheepskin

The skin of numerous varieties of sheep, employed for fine leather for many uses. The best sheepskins come from the sheep yielding the poorest wool. When the hair is short, coarse, and sparse, the nourishment goes into the skin. The merino types having fine wool have the poorest pelts. Wild sheep and the low-wool crossbreeds of India, Brazil, and South Africa have close-fibered, firm pelts comparable in strength with some kidskin, and retain the softness of sheepskin. This type of sheepskin from the hair sheep is termed *cabretta* and is used almost entirely for making gloves and for shoe uppers. None is produced in the United States. The commercial difference between sheepskin and *lambskin* is one of weight only. Sheepskins usually run 3–3.5 lb (1.4–1.6 kg) per skin without wool, and lambskins are those below 3 lb (1.4 kg). Sheepskins are tanned with alum, chrome, or sumac. The large heavy skins from Argentina and Australia are often split, and the grain side tanned in sumac for bookbinding and other goods; the flesh side is tanned in oil or formaldehyde and marketed as chamois. The fine-grained sheepskin from Egypt, when skived and especially treated, are known as *mocha leather*. *Uda skins* and *white fulani skins*, from Nigerian sheep, are used for good-quality grain and suede glove leather. *Sheepskin shearlings* are skins taken from heavy-wooled sheep a few weeks after shearing. They are tanned with the wall on, and the leather is used for aviation flying suits and for coats.

Sheet

A flat-rolled metal product of some maximum thickness and minimum width arbitrarily dependent on the type of metal. It has a width-to-thickness ratio greater than about 50. Generally, such flat products under 6.5 mm (1/4 in.) thick are called sheets, and those 6.5 mm (1/4 in.) thick and over are called plates. Occasionally, the limiting thickness for steel to be designated as sheet steel is No. 10 Manufacturer's Standard Gauge for sheet steel, which is 3.42 mm (0.1345 in.) thick.

Sheet Forming

The plastic deformation of a piece of sheet metal by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristics.

Sheeting

A form of plastic in which the thickness is very small in proportion to length and width and in which the plastic is present as a continuous phase throughout, with or without filler.

Sheet Metal Forming

This is the process of shaping thin sheets of metal (usually less than 6 mm) by applying pressure through male or female dies or both. Parts formed of sheet metal have such diverse geometries that it is difficult to classify them. In all sheet-forming processes, excluding

shearing, the metal is subjected to primarily tensile or compressive stresses or both. Sheet forming is accomplished basically by processes such as stretching, bending, deep drawing, embossing, bulging, flanging, roll forming, and spinning. In most of these operations, there are no intentional major changes in the thickness of the sheet metal.

There are certain basic considerations that are common in all sheet forming. Grain size of the metal is important in that too large a grain produces a rough appearance when formed, a condition known as orange peel. For general forming, an American Society for Testing and Materials (ASTM) No. 7 grain size (average grain diameter 32 μm) is recommended. Another type of surface irregularity observed in materials such as low carbon steel is the phenomenon of yield-point elongation that results in stretcher strains or Lueder's bands, which are elongated depressions on the surface of the sheet. This is usually avoided by cold-rolling the original sheet with a reduction of only 1%–2% (temper rolling). Since yield-point elongation reappears after some time because of aging, the material should be formed within this time limit. Another defect is season cracking (stress cracking, stress corrosion cracking), which occurs when the form part is in a corrosive environment for some time. The susceptibility of metals to season cracking depends on factors such as type of metal, degree of deformation, magnitude of residual stresses in the formed part, and environment.

Anisotropy or directionality of the sheet metal is also important because the behavior of the material depends on the direction of deformation. Anisotropy is of two kinds: one in the direction of the sheet plane and the other in the thickness direction. These aspects are important, particularly in deep drawing.

Formability of sheet metals is of great interest, even though it is difficult to define this term because of the large number of variables involved. Failure in sheet forming usually occurs by localized necking or buckling or both, such as wrinkling or folding. For a simple tension-test specimen, the true (natural) necking strain is numerically equal to the strain-hardening exponent of the material; thus, for example, commercially pure annealed aluminum or common 304 stainless steel stretches more than cold-work steel before it begins to neck. However, because of the complex stress systems in most forming operations, the maximum strain before necking is difficult to determine, although some theoretical solutions are available for rather simple geometries.

Considerable effort has been expended to simulate sheet-forming operations by simple tests. In addition to bands or tear tests, cupping test have also been commonly used, such as the Swift, Olsen, and Erichsen tests. Although these tests are practical to perform and give some indication of the formability of the sheet metal, they generally cannot reproduce the exact conditions to be encountered in actual forming operations.

Stretch Forming

In this process, the sheet metal is clamped between jaws and stretched over a form block. The process is used in the aerospace industry to form large panels with varying curvatures. Stretch forming has the advantages of low die cost, small residual stresses, and virtual elimination of wrinkles in the formed part.

Bending

This is one of the most common processes in sheet forming. The part may be bent not only along a straight line but also along a curved path (stretching, flanging). The minimum bend radius, measured to the inside surface of the bend, is important and determines the limit

S

at which the material cracks either on the outer surface of the bend or at the edges of the part. This radius, which is usually expressed in terms of multiples of the sheet thickness, depends on the ductility of the material, width of the part, and its edge conditions.

Springback in bending and other sheet-forming operations is due to the elastic recovery of the metal after it is deformed. Determination of springback is usually done in actual tests. Compensation for springback and practice is generally accomplished by overbending the part; adjustable tools are sometimes used for this purpose.

In addition to male and female dies used in most bending operations, the female die is replaced with a rubber pad. In this way, die cost is reduced and the bottom surface of the part is protected from scratches by a metal tool. The roll-forming process replaces the vertical motion of the dies by the rotary motion of rolls with various profiles. Each successive roll bends the strip a little further than the preceding roll. The process is economical for forming long sections in large quantities.

Rubber Forming

Although many sheet-forming processes are carried out in a press with male and female dies usually made of metal, there are four basic processes that utilize rubber to replace one of the dies. Rubber is a very effective material because of its flexibility and low compressibility. In addition, it is low in cost, is easy to fabricate into desired shapes, has a generally low wear rate, and also protects the workpiece surface from damage.

The simplest of these processes is the Guerin process. Auxiliary devices are also used in forming more complicated shapes. In the Verson–Wheeler process, hydraulic pressure is confined in a rubber bag, the pressure being about five times greater than that in the Guerin process. For deeper draws, the Marform process is used. This equipment is a package unit that can be installed easily into a hydraulic press. In deep drawing of critical parts, the hydroform process is quite suitable, where pressure in the dome is as high as 100 MPa. A particular advantage of this process is that the formed portions of the part travel with the punch, thus lowering tensile stresses, which can eventually cause failure.

Bulging of tubular components, such as coffee pots, is also carried out with the use of a rubber pad placed inside the workpiece; the part is then expanded into a split female die for easy removal.

Deep Drawing

A great variety of parts are formed by this process, the successful operation of which requires a careful control of factors such as blank-holder pressure, lubrication, clearance, material properties, and die geometry. Depending on many factors, the maximum ratio of blank diameter to punch diameter ranges from about 1.6 to 2.3.

This process has been extensively studied, and the results show two important material properties for deep drawability are the strain-hardening exponent and the stress ratio (anisotropy ratio) of the metal.

Spinning

The process forms parts with rotational symmetry over a mandrel with the use of a tool or roller. There are two basic types of spinning: conventional or manual spinning, and shear spinning. The conventional spinning process forms the material over a rotating mandrel with little or no change in the thickness of the original blank. Parts can be as large as 6 m in diameter. The operation may be carried

out at room temperature or higher for materials with low ductility or greater thickness. Success in manual spinning depends largely on the skill of the operator. The process can be economically competitive with drawing; if a part can be made by both processes, spinning may be more economical than drawing for small quantities.

In shear spinning (hydrospinning, flturning), the deformation is carried out with a roller in such a manner that the diameter of the original blank does not change but the thickness of the part decreases by an amount dependent on the mandrel angle. The spinability of a metal is related to its tensile reduction of area. For metals with a reduction of area of 50% or greater, it is possible to spin a flat blank to a cone of an included angle of 3° in one operation. The shear spinning produces parts with various shapes (conical, curvilinear, and also tubular by tube spinning on a cylindrical mandrel) with good surface finish, close tolerances, and improved mechanical properties.

Miscellaneous Processes

Many parts require one or more additional processes; some of these are described briefly here. Embossing consists of forming a pattern on the sheet by shallow drawing. Coining consists of putting impressions on the surface by a process that is essentially forging; the best example is the two phases of a coin.

Coining pressures are quite high, and control of lubrication is essential to bring out all the fine detail in a design. Shearing is separation of the material by the cutting action of a pair of sharp tools, similar to a pair of scissors. The clearance in shearing is important to obtaining a clean-cut. A variety of operations based on shearing are punching, blanking, perforating, slitting, notching, and trimming.

Die materials used are cast alloys, die steels, and cemented carbides for high-production work. Nonmetallic materials such as rubber, plastics, and hardwood are also used as die materials. The selection of the proper lubricant depends on many factors, such as die and workpiece materials, and severity of the operation. A great variety of lubricants are commercially available, such as drawing compounds, fatty acids, mineral oils, and soap solutions.

Pressures in sheet-metal forming generally range between 7 and 55 MPa (normal to the plane of the sheet); most parts require about 10 MPa.

Sheet Metal Parts

Stamping and pressing make up a large family of metal-forming processes. Included in this group are blanking, pressing, stamping, and drawing, all of which are used to cut or form metal plate, sheet, and strip. The steps common in all stamping and pressing operations are the preparation of a flat blank and shearing or stretching the metal into a die to attain the desired shape.

In drawing, the flat stock is either formed in a single operation, or progressive drawing steps may be needed to reach the final form. In spinning, flat disks are dished by a tool as they revolve on a lathe.

Stamping involves placing the flat stock in a die and then striking it with a movable die or punch. Besides shaping the part, the dies can perform perforating, blanking, bending, and shearing operations. Almost all metals can be stamped. In general, stampings are limited to metal thicknesses of 9.5 mm or less. Pressing and drawing operations can be performed on cold metals up to 19 mm thick and up to about 89 mm on hot metals.

In recent years, many new press-forming and drawing techniques have been developed. A number of them make use of rubber pads, bags, and diaphragms as part of the die or forming elements.

Some involve stretch forming over dies. Others combine forming and heat-treating operations. And still other methods, known as high-energy rate forming, employ explosive, electrical, or magnetic energy to produce shockwaves that form the material into the desired shape.

Stamping

Frequently, secondary operations, such as annealing in furnaces, trimming in lathes or rolls, brake bends, and tapping, make it difficult to define a part as a stamping. Such operations, as well as finishing operations, may cost more than comparatively fast and economical press operations.

Sizes and Materials

Presses and presslike machines are not necessarily limited to sheet-metal forming. They punch paper doilies and cut uppers for shoes. Multislide machines form round or flat wire; some presses impact-extrude aluminum, zinc, and steel into deep shells for toothpaste tubes or shell bodies, using slugs cut from bars, or cast for the purpose, or sometimes punched from sheets and plates, in bellmouth dies to burnish the edges. Presses forge from billets and they compress powdered metal and carbon into compacts.

Types of Work

Presses perform such operations as blanking (some blanks are made on shears) and cutting off; piercing (punching) holes, cutouts, or extruding holes; bending to almost any angle (this would include lance forming of tabs); embossing; or forming strengthening ribs or shallow pockets and hemming (bending edges up and then back flat on themselves). The edges of shells may be curled in or out. Coining changes thicknesses, for the raw material of stamping is almost always uniform.

Related to blanking are trimming operations to remove excess stock and shaving, a slight removal of stock. Examples are the first step of broaching to obtain close tolerances, small teeth, and straight edges where the breakout on stampings is objectionable, or to improve edge appearance to about 125 $\mu\text{in.}$ on thinner materials, and about 150 $\mu\text{in.}$ on stock 2.3 mm and over.

Sheet Molding Compound

Sheet molding compound (SMC) combine with matched-metal-die compression molding has been the most successful glass fiber composite in automotive exterior body panel applications. In the medium and heavy truck market, SMC is a clear winner. In the more aesthetically demanding car market, however, SMC remains a niche player relegated to medium-volume specialty vehicles. More recent successes point to a shift in focus to more functional and structural applications.

The most successful applications address the total system needs and offer unmatched value in terms of high quality, dependability, and cost-effectiveness. The radiator support assembly is such a case. This illustrates that SMC can win and retain large volume applications resulting in profitable growth. SMC solutions are perhaps the best known and most developed and thus offer valuable lessons for all composites.

A thermoset composite of fibers, usually an unsaturated polyester resin, and pigments, fillers, and other adhesives that have been compounded and processed into sheet form to facilitate handling

and the subsequent compression molding operation (generally cross linked with styrene).

SMC Developments

Compression-molded SMC is perhaps the most talked about composite system for automotive applications. SMC is a versatile composite capable of satisfying structural and aesthetic needs at fast molding cycles, and it is suitable for large production volumes.

SMC is an accepted and commercially proven material for automotive part manufacture, serving the role of composite ambassador to the automotive world. SMC offers capital efficiency vs. steel. Capital efficiency makes SMC a viable option for both styling differentiation and new capacity expansion.

Because of longer cycles and more defects, however, the cost of low-density SMC remains high, relegating it to but a few niche applications. This illustrates that the tension resulting from simultaneous needs of the original equipment manufacturers (OEMs) for low-cost and weight reduction cannot be resolved with higher-cost technology.

SMC applications fall into three major categories: functional, structural, and appearance. Recent gains and functional applications, such as oil pans and heat shields, have been impressive. The main driver of this achievement has been resin development. Both elevated temperature and oil resistance needs are now being met with polyester resins, which are less expensive than the vinyl esters previously employed.

Structural applications offer deeper insights into the capabilities and limitations of the SMC. Two such applications, the radiator support assembly and cross car beam, illustrate the capability of SMC for parts consolidation. Yet the former leads to a low-cost product, whereas the latter remains a premium niche component. Some reasons behind this outcome can be explained from the total system perspective.

Appearance or Class A applications are of importance to both growth and survival of SMC. The opportunity for SMC in this arena is huge and significant inroads have been made. Yet SMC has penetrated only a small fraction of this potential and only, to a significant degree, in the United States. The battle with steel in this arena has been examined using cost models.

Structural Applications

Structural applications attempt to exploit the design freedom and parts consolidation potential of SMC leading to integration of multiple functional roles. Integrated front-end system design, for the Ford Taurus and Mercury Sable, incorporates an upper and lower radiator support molded in SMC. The lower radiator support consolidates 22 steel parts into two SMC parts, resulting in a 14% cost reduction vs. steel.

Another application for SMC is cross car beams, which are also known as supported instrument panels. Because of their use on light truck platforms, cross car beams consume significant amounts of SMC. The level of functional integration is as large as in the case of the radiator support but the end result is very different. The added complexity pushes the boundaries of SMC flow and moldability. To make matters worse, attempts have been made to use very low density SMC, resulting in even more molding difficulties. In the end, low-cost has not been achieved, making both OEMs and molders unhappy. Perhaps a simpler design, incorporating a steel structural insert, might be more successful.

These two examples illustrate that parts consolidation is a useful tool for achieving low-cost; however, there are limits to this

S

approach and often the increased complexity leads to higher cost than in an equivalent system of many specialized components.

Sheet Separation

In spot, seam, or projection welding, the gap that exists between faying surfaces surrounding the weld, after the joint has been welded.

Sheffield Plate

Decorative electrodeposited silver plating or copper or nickel silver.

Shelf Life

The length of time a material, substance, product, or reagent can be stored under specified environmental conditions and continue to meet all applicable specification requirements and/or remain suitable for its intended function.

Shelf Roughness

Roughness on upward-facing surfaces where undissolved solids have settled on parts during a plating operation.

Shell

(1) A hollow structure or vessel. (2) An article formed by deep drawing. (3) The metal sleeve remaining when a billet is extruded with a dummy block of somewhat smaller diameter. (4) In shell molding, a hard layer of sand and thermosetting plastic or resin formed over a pattern and used as the mold wall. (5) A tubular casting used in making seamless drawn tube. (6) A pierced forging.

Shellac

A product where an insect lives on various trees of southern Asia. The larvae of the lac insect settle on the branches, pierce the bark, and feed on the sap. The lac secretion produced by the insects forms a coating over their bodies and makes a thick incrustation over the twig. Eggs developed in the females are deposited in a space formed in the cell, and the hatched larvae emerge. This forming continues for 3 weeks and is repeated twice a year. The incrustation formed on the twigs is scraped off, dried in the shape, and is the commercial *stick lac*. It contains woody matter, lac resin, lac die, and bodies of insects. *Seed lac* is obtained by screening, grinding, and washing stick lac. The washing removes the lac die. *Lac die* was once an important dyestuff, giving about the same colors as cochineal but not as strong.

Shellac is prepared from seed lac by melting or by extraction with solvents. The molten material is spread over a hot cylinder and stretched, and the cooled sheet is broken into flakes of shellac. When pure, shellac varies from pale orange to lemon yellow, but the color of commercial shellac may be due to a high content of common resin. *White shellac* is made by bleaching with alkalis.

Hard lac has the soft constituents removed by solvent extraction. For electrical use, the wax content should be below 3.5%. By solvent extraction of the seed lac, the wax may be reduced to 1%. Shellac is graded by color and by its freedom from dirt. The first grade contains no resin, but other grades may contain up to 12%.

Most Indian exports of seed lac to the United States are of the special grade, which has a high bleach index. *Cut shellac* is shellac dissolved in alcohol but usually mixed with a high percentage of resin. Shellac has good adhesive properties and high dielectric strength, and is used in adhesives, varnishes, floor waxes, insulating compounds, and some molding plastics. Hard-face wax polishes contain a high percentage of shellac, up to 80%, to conserve carnauba and other waxes.

Shell Core

A shell-molded sand core.

Shell Hardening

A surface-hardening process in which a suitable steel workpiece, when heated through and quench hardened, develops a martensite layer or shell that closely follows the contour of the piece and surrounds a core of essentially pearlitic transformation product. This result is accomplished by a proper balance among section size, steel hardenability, and severity of quench.

Shelling

(1) A term used in railway engineering to describe an advanced phase of *spalling*. (2) A mechanism of deterioration of coated abrasive products in which the entire abrasive grains are removed from the cement coating that held the abrasive to the backing layer of the product.

Shell Mold Castings

Shell mold casting is a process that uses relatively thin-wall mold made by bonding silica or zircon sand with a thermosetting phenolic or urea resin. It has gained widespread use because it offers many advantages over conventional sand castings. Shell mold casting is a practical and economical way to meet the demand for weight reduction, thinner sections, and closer tolerances.

Advantages

There are five basic advantages:

1. Lower costs. High production rates and fewer finishing operations result in a lower unit cost for applicable parts.
2. Closer tolerances. Shell castings have closer tolerances than sand castings. Draft allowances are also reduced.
3. Smoother surface finish. Shell molding provides an improved surface compared with sand casting (250–1000 $\mu\text{in. rms}$ for sand, 125–250 for shell).
4. Less machining. The precision of shell molding reduces, and in many cases eliminates, machining or grinding operations.
5. Uniformity. Insulating properties of the molds produce casting surfaces free of chill and with a more uniform grain structure.

Although a shell mold is more expensive than a green sand mold, the possibility of reducing weight, minimizing machining, and eliminating cores often result in savings sufficient to offset the mold cost.

The Process

The shell molding process can be broken down into five operations:

1. A match plate pattern is made from tool steel with dimensions calculated to allow for subsequent metal shrinkage.
2. The resin-sand mixture is applied to the metal pattern, which is then heated to 218°C–232°C. The hot pattern melts the resin, which flows between the grains of sand and binds them together. Thickness of the mold increases with time. After the desired thicknesses are reached, excess unbonded sand is poured from the pattern.
3. The pattern, with the soft shell adhering, is placed in an oven and heated to 566°C–649°C for 30 s to 1 min. This cures the shell and produces a hard, smooth mold that reproduces the pattern surface exactly. The shell is stripped from the pattern by ejector pins. The other half of the mold is produced in the same way.
4. Sprues and risers are opened and cores inserted to complete the cope and drag halves of the mold.
5. The two shell halves are glued together under pressure to form a tightly sealed mold that can be stacked and stored indefinitely.

Shell Molded Cores

Shell molded cores are an offshoot of the shell molding process. These cores have several advantages over the sand cores that they replace: the shell core usually costs less than the sand core; strength and rigidity permit handling without damage or distortion; sharp details, including threads, are accurately reproduced; core weight is reduced; cured cores are unaffected by moisture and can be stored for long periods of time; most shell cores are hollow and can function as vents during casting.

Shell Molding

A foundry process in which a mold is formed from thermosetting resin-bonded sand mixtures brought in contact with preheated (150°C–260°C) metal patterns, resulting in a firm shell with a cavity corresponding to the outline of the pattern. Also called *Croning process*.

Shell Tooling

A mold or bonding fixture for forming plastic parts that consists of a contoured surface shell supported by a substructure to provide dimensional stability.

Shielded Carbon Arc Welding

A carbon arc welding process variation that produces coalescence of metals by heating them with an electric arc between a carbon electrode and the work. Shielding is obtained from the combustion of a solid material fed into the arc or from a blanket of flux on the work, or both. Pressure may or may not be used, and filler metal may or may not be used.

Shielded Metal Arc Cutting

A metal arc cutting process in which metals are severed by melting them with the heat of an arc between a covered metal electrode and the base metal.

Shielded Metal Arc Welding (SMAW)

A manual arc welding process in which the heat for welding is generated by an arc established between a flux-covered consumable electrode in a workpiece. The electrode tip, molten metal pool, arc, and adjacent areas of the workpiece are protected from atmospheric contamination by a gaseous shield obtained from the combustion and decomposition of the electrode covering. Additional shielding is provided for the molten metal in the weld pool by a covering of molten flux or slag. Filler metal is supplied by the core of the consumable electrode and from metal powder mixed with the electrode covering of certain electrodes. Shielded metal arc welding is often referred to as arc welding with stick electrodes, manual metal arc welding, and stick welding.

Shielding

(1) A material barrier that prevents radiation or a flowing fluid from impinging on an object or a portion of an object. (2) In an electron-optical instrument, the protection of the electron beam from distortion due to extraneous electric and magnetic fields. Because the metallic column of the microscope is at ground potential, it provides electrostatic shielding. See also *magnetic shielding*. (3) Placing an object in an electrolytic bath so as to alter the current distribution on the cathode. A nonconductor is called a shield; a conductor is called a *robber*, a thief, or a guard.

Shielding Gas

(1) Protective gas used to prevent atmospheric contamination during welding. (2) A stream of an inert gas directed at the substrate during thermal spraying so as to envelop the plasma flame and substrate; intended to provide a barrier to the atmosphere in order to minimize oxidation.

Shift

A casting imperfection caused by mismatch of cope and drag or of cores and molds.

Shim

A thin piece of material used between two surfaces to obtain a proper fit, adjustment, or alignment.

Shimmy Die

See *flat edge trimmer*.

Shock Load

The sudden application of an external force that results in a very rapid buildup of stress—for example, piston loading in internal combustion engines.

Shoe

(1) A metal block used in a variety of bending operations to form or support the part being processed. (2) An anvil cap or *sow block*. (3) A device for gathering filaments into a strand, in glass fiber forming. See the term *glass filament bushing*.

S

Shore Hardness

A measure of the resistance of material to indentation by a spring-loaded indenter during scleroscope hardness testing. The higher the number, the greater the resistance. Normally used for rubber materials. See also *scleroscope hardness test*.

Short

An imperfection in a molded plastic part due to an incomplete fill. In reinforced plastics, this may be evident either from an absence of surface film in some areas or as lighter, unfused particles of material showing through a covering surface film, accompanied possibly by thin-skin blisters. In thermoplastics, also called *short-shot*.

Short Beam Shear

A flexural test of a plastic specimen having a low test span-to-thickness ratio (e.g., 4:1), such that failure is primarily in shear.

Short Circuiting Transfer

In consumable-electrode arc welding, a type of metal transfer similar to globular transfer, but in which the drops are so large that the arc is short-circuited momentarily during the transfer of each drop to the weld pool. See also *gas metal arc welding* and compare with *globular transfer* and *spray transfer*.

Shortness (Adhesives)

A qualitative term that describes an adhesive that does not string cotton, or otherwise form filaments or threads during application.

Shortness (Metals)

A form of brittleness in metal. It is designated as *cold shortness* or *hot shortness* to indicate the temperature range in which the brittleness occurs.

Shorts

The product that is retained on a specified screen in the screening of a crushed or ground material. See also *plus sieve*.

Short Shot

Insufficient injection of material into the mold during forming of plastics or composites.

Short-Term Etching

In metallographic preparation of specimens, etching times of seconds to a few minutes.

Short Transverse

See *transverse*.

Shot

(1) Small, spherical particles of metal. (2) The injection of molten metal into a die casting die. The metal is injected so quickly that it can be compared to the shooting of a gun.

Shotblasting

Blasting with metal *shot*; usually used to remove deposits or mill scale more rapidly or more effectively than can be done by *sandblasting*.

Shot Capacity

In forming plastic parts, the maximum weight of material an injection machine can provide from one forward motion of the ram, screw, or plunger.

Shot Peening

A method of cold working metals in which compressive stresses are induced in the exposed surface layers of parts by the impingement of a stream of *shot*, directed at the metal surface at high velocity under controlled conditions. It differs from blast cleaning in primary purpose and in the extent to which it is controlled to yield accurate and reproducible results. Although shot peening cleans the surface being peened, this function is incidental. The major purpose of shot peening is to increase fatigue strength. Shot for peening is made of iron, steel, or glass.

Shotting

The production of *shot* by pouring molten metal in finely divided streams. Solidified spherical particles are formed during descent in a tank of water.

Shoulder

See preferred term *root face*.

Shrinkage (Ceramics)

The fractional reduction in dimensions or volume of a material or object when subjected to drying, calcining, or firing (sintering).

Shrinkage (Metals)

- (1) The contraction of metal during cooling after hot forging. Die impressions are made oversize according to precise shrinkage scales to allow the forgings to shrink to design dimensions and tolerances.
- (2) See *casting shrinkage*.

Shrinkage (Plastics)

The relative change in dimension from the length measured on the mold when it is cold to the length of the molded plastic object 24 h after it has been taken out of the mold.

Shrinkage Cavity

A void left in cast metal as a result of solidification shrinkage. Shrinkage cavities can appear as either isolated or interconnected irregularly shaped voids. See also *casting shrinkage*.

Shrinkage Rule

A measuring ruler with graduations expanded to compensate for the change in the dimensions of the solidified casting as it cools in the mold.

Shrinkage Stress

See preferred term *residual stress*.

Shrinkage Void

A cavity type discontinuity in weldments normally formed by shrinkage during solidification.

Shrink Fit

An *interference fit* produced by heating the outside member of mating parts to a practical temperature for easy assembly. Usually the inside member is kept at or near room temperature. Sometimes the inside member is cooled to increase ease of assembly.

Shrink Forming

Forming of metal wherein the inner fibers of a cross section undergo a reduction in a localized area by the application of heat, cold upset, or mechanically induced pressures.

Shroud

A protective, refractory-lined metal-delivery system to prevent reoxidation of molten steel when it is poured from ladle to tundish to mold during continuous casting.

Shunt

A device used to divert part of an electric current.

Shut Height

For a metal forming press, the distance from the top of the bed to the bottom of the slide with the stroke down and adjustment up. In general, it is the maximum die height that can be accommodated for normal operation, taking the *bolster plate* into consideration.

SI

See *silicones*.

Sialon

Sialon is a generic term for a family of compositions produced by reacting silicon nitride with aluminum oxide and aluminum nitride at high temperatures. In other words, a sialon is a silicon nitride-base ceramic in which some of the silicon has been replaced with aluminum and some of the nitrogen with oxygen, resulting in a substituted solid solution referred to as β' -sialon with a compositional range of $\text{Si}_{6-x}\text{Al}_x\text{O}_x\text{N}_{8-x}$ based on the β - Si_3N_4 unit cell. Two major types have been developed commercially, one consisting of β' grains in a semicontinuous intergranular crystalline phase of yttrium-aluminum-garnet (YAG). Parts made from β' -sialon are produced by cold isostatically pressing the powder, followed by sintering at a maximum temperature of 1800°C for approximately 1 h; yttrium oxide is used as a sintering aid.

A solid solution based on the alpha silicon nitride structure has received less attention, but α' -sialon shows promise commercially because it has greater hardness than β' -sialon. In addition, it offers

an improved product with less grain-boundary glass as a result of the incorporation of the cation from the sintering additive (e.g., Y_2O_3) into a solid solution of $\text{M}_x(\text{Si}, \text{Al})_{12}(\text{O}, \text{N})_{16}$ based on the α - Si_3N_4 unit cell. Currently, single-phase α' -sialons are only available in hot pressed or hot isostatically pressed forms, but composites of $\beta' + \alpha'$ are available produced by pressureless sintering.

Properties of sialons, which are based on the sintering aids used in the fabrication route followed, are similar to silicon nitride. The advantages of sialons are their low coefficient of thermal expansion ($2\text{--}3 \times 10^{-6}/^\circ\text{C}$) and good oxidation resistance. The array of applications for sialons is also similar to that of silicon nitride—namely, automotive applications in machine tool cutting inserts for machining difficult-to-cut materials such as cast irons in wrought nickel-base superalloys.

Side Corings

In forming of plastics, projections that are used to core a hole in a direction other than the line of closing of a mold, and that must be withdrawn before the part is ejected from the mold. Also called side draw pins.

Side Cutting-Edge Angle

See the term *single-point tool*.

Side Milling

Milling with cutters having peripheral and side teeth. They are usually profile sharpened but may be form relieved. See also *milling*.

Side Rake

In a single-point turning tool, the angle between the tool face and a reference plane, corresponding to radial rake in milling. It lies in a plane perpendicular to the tool base and parallel to the rotational axis of the work. See the term *single-point tool*.

Side Thrust

The lateral force exerted between the dies by reaction of a forged piece on the die impressions.

Siemens (S)

A unit of electrical conductivity. One siemens of conductance per cubic meter with a potential of 1 V allows the passage of 1 A/m². See also *conductance* (electrical).

Sieve

A standard wire mesh or screen used in graded sets to determine the mesh size or particle size distribution of particulate and granular solids. Sieves are stacked in order, with the largest mesh size at the top and a pan at the bottom. An appropriate sample weight of powder is spread on the top sieve and covered. The stack of sieves is agitated in a prescribed manner (shaking, rotating, or tapping) for a specified period of time. The powder fractions remaining on each sieve and contained in the bottom pan are weighed separately and reported as percentages retained or passed by each sieve. See also *sieve analysis*.

S

Sieve Analysis

A method of determining *particle size distribution*, usually expressed as the weight percentage retained upon each of a series of standard screens of decreasing mesh size. For example, a typical sieve analysis for titanium powder is as follows:

Mesh Size (U.S.)	Particle Size (μm)	Weight Percent Retained
+80	+177	0
−80 + 100	−177 + 149	0.1
−100 + 140	−149 + 105	11.2
−140 + 200	−105 + 74	32.9
−200 + 230	−74 + 64	5.0
−230 + 325	−64 + 45	23.3
−325	−45	27.5

Using the standard sieve designations and screen openings sizes, a user can determine that −140 + 299 powder is smaller than approximately 105 μm, yet larger than approximately 74 μm, that is, −33% is retained on the 200 mesh screen.

Sieve Classification

The separation of powder into particle size ranges by the use of a series of grated sieves. Also called screen analysis.

Sieve Fraction

That portion of a powder sample that passes through a sieve of specified number and is retained by some finer mesh sieve of specified number. See also *sieve analysis*.

Sieve Shaker

A device for shaking, knocking, or vibrating a single sieve or a stack of sieves. It consists of a frame, a motorized knocker, shaker or vibrator, and fasteners for the sieve(s).

Sieve Underside

The underside of the mesh to which loose powder often adheres. To ensure accuracy of a sieve analysis, this material must be removed and included in the weight determination.

Sigma Bonding

Covalent bonding between atoms in which *s* orbitals or hybrid orbitals between *s* and *p* electrons overlap in cylindrical symmetry along the axis joining the nuclei of the atoms. See also *pi bonding*.

Sigma Phase

A hard, brittle, nonmagnetic intermediate phase with a tetragonal crystal structure, containing 30 atoms per unit cell, space group, *P4/mnm*, occurring in many binary and ternary alloys of the transition elements. The composition of this phase in the various systems is not the same, and the phase usually exhibits a wide range in homogeneity. Alloying with a third transition element usually enlarges the field homogeneity and extends it deep into the ternary section.

Sigma-Phase Embrittlement

Embrittlement of iron–chromium alloys (most notably austenitic stainless steels) caused by precipitation at grain boundaries of the hard, brittle intermetallic *sigma phase* owing to long periods of exposure to temperatures between approximately 560°C and 980°C. Sigma-phase embrittlement results in severe loss in *toughness* and *ductility*, and can make the embrittled material susceptible to *intergranular corrosion*. See also *sensitization*.

Signal-to-Noise Ratio

(1) The ratio of the amplitude of a desired signal at any time to the amplitude of noise signals at the same time. (2) Ratio of the average response to the root-mean-square variation about the average response. Ratio of variances associated with the two parts of the performance measurement. See also *noise*.

Significance Level

The stated probability (risk) that a given test of significance will reject the hypothesis that a specified effect is absent when the hypothesis is true.

Significant

Statistically significant. An effect of difference between populations is said to be present if the value of a test statistic is significant, that is, lies outside the predetermined limits. See also *population*.

Silica (SiO₂)

The common oxide of silicon usually found naturally as quartz or in complex combination with other elements such as silicates. Various polymorphs and natural occurrences of silica include cristobalite, tridymite, cryptocrystalline chert, flint, chalcedony, and hydrated opal. Silica is the primary ingredient of sand, refractories, and glass.

Silica, as the dioxide of silicon is commonly termed, is the principal constituent of the solid crust of the Earth. Consequently, it is a major ingredient of most of the nonmetallic, inorganic materials used in industry. Silica occurs in a number of allotropic forms, which have different properties and uses.

The principal modifications of silica are quartz, silica glass, cristobalite, and tridymite. The last two are sometimes combined under the term of inverted silica. The valuable physical properties of these four principal modifications lead to a wide variety of applications for silica in industry and technology.

Quartz

The common low-temperature form of silica, quartz, is strong and insoluble in water. Consequently, sandstone, which is composed of grains of quartz held together by a siliceous cement, is an excellent building stone. Huge quantities of silica stone are used as aggregate for concrete. One curious variety has a structure that renders the rock flexible and is known as itacolumite or flexible sandstone. Quartzite, in which the quartz grains of an original sandstone have recrystallized and grown to a compact mass, and vein quartz are too hard and difficult to shape for use as building stones.

Rock crystal, as the euhedral quartz found in nature is termed, is often carved into ornaments of great beauty because of its perfect transparency and because of the high luster it produces by polishing.

The “crystal ball” of story and romance is a polished quartz sphere. Colored varieties of quartz are much valued as semiprecious stones. The purple amethyst, blue sapphire quartz, yellow citrine or false topaz, red or pink rose quartz, smoky quartz, and the dark brown morion are examples.

Sandstone is also useful as an abrasive. It is used for grindstones and pulpstones. “Berea” grit from northern Ohio and novaculite from Arkansas are examples of coarse and fine-grained natural stones that are still preferred for some purposes to the artificial abrasives made from silicon carbide or aluminum oxide.

The strength and hardness of various material forms of silica leads to use for crushing and for grinding. Flint pebbles are used in ball mills for grinding all sorts of materials. Agate mortars are insoluble in the chemical laboratory for pulverizing minerals before analysis. Sandstone and quartzite are used for millstones and buhrstones to crush and grind grain, paint pigments, fertilizers, and many other products. Quartz sand, driven by compressed air, constitutes the useful sandblast for cleaning metal, decorating glass, and refacing stone buildings. Coated on paper, quartz grains provide the carpenter and cabinet maker with the familiar “sandpaper,” although much modern sandpaper is really coated with crushed glass containing only about 70% silica.

The abrasive properties of quartz grains are also employed by locomotives to gain traction on steel rails, in billiard cue chalk, and in the chicken gizzard, where quartz grains are used as a kind of natural ball mill.

The thermal properties of the various forms of silica also lead to important uses. Its high melting point (1710°C) makes it a good refractory, while its low cost and low thermal expansion have brought about a wide use in industrial furnaces, particularly for melting steel and glass.

Properties

In general, the thermal expansion of all of the common forms of silica is low at high temperatures. This makes silica refractories capable of withstanding sudden temperature changes and large thermal gradients very well in these high-temperature ranges. At lower temperatures, large volume changes, due to rapid inversions from a high-temperature crystalline forms of quartz, tridymite, cristobalite, to corresponding low-temperature forms, make these materials rather sensitive to sudden temperature changes. The low-temperature forms of quartz, tridymite and cristobalite, also have higher thermal expansions than the high-temperature forms and the amorphous form of silica. This form of silica, variously known as silica glass, vitrosil, and fused quartz, is thus the only form of silica that may be heated rapidly from room temperature without fear of breakage. A further limitation on the thermal behavior of silica refractories is occasioned by the large volume increase that occurs as quartz changes slowly to tridymite or cristobalite at temperatures above 870°C. This may lead to swelling and warping of silica bricks if they are not first converted to the forms stable at high temperatures by prolonged firing. Because the volume changes that occur when tridymite changes from its high-temperature form to the forms stable at lower temperatures are less than the corresponding change for cristobalite, an effort is made to convert the silica refractory as completely to tridymite as is feasible before using it.

Uses

Silica bricks are made from crushed quartzite rock, known as ganister, which is bonded with 1.5%–3.0% of lime. They are molded smaller than the dimensions desired in the finished brick to allow

for an expansion of about 3/8 in./ft as the quartz inverts to tridymite during firing. A firing schedule of about 20 days at 1450°C (about cone 16) is required. Study of the phase diagram of the silica–lime system shows why considerable quantities of lime may be used to bond the quartzite in silica bricks without loss of refractoriness. The lime is taken up in an immiscible lime-rich glass phase of which only a small amount is formed because of its high lime content.

In use, silica bricks are characterized by retention of rigidity and load-bearing capacity to temperatures above 1600°C, without the slow yield characteristic of fireclay brick. If a cold silica brick is heated suddenly, it spalls and disintegrates owing to the sudden volume changes taking place at the high–low inversions of tridymite and cristobalite. If heated cautiously through this sensitive temperature region, silica brick is very resistant to temperature shock.

The refractory properties of quartz sand are also employed in molds for cast iron. Huge quantities of sand, with varying amounts of clay impurity to bond the grains, are used for this purpose in the foundries of the world.

Crystal quartz in piezoelectric oscillators have become indispensable for the control of radio transmitters, radar equipment, and other electronic “timing” gear.

This use and other electrical and optical uses of crystal quartz depend upon the symmetry of the material. Some experts state that low quartz is the most important and most familiar example of the trigonal enantiomorphous hemihedral or trigonal trapezohedral class of symmetry. This class is characterized by one axis of threefold symmetry with three axes of twofold symmetry perpendicular thereto and separated by angles of 120°. This class has no plane of symmetry and no center of symmetry.

Optical Properties

The transparency of crystal quartz, particularly to the short waves of the ultraviolet, makes it very useful in optical instruments. Quartz prisms are employed in spectrographs for analysis of light waves varying in length from almost 5 μm in the infrared to almost 0.2 μm in the ultraviolet. Lenses made of crystal quartz are also useful over this range for photography and microscopy. Crystal quartz is more transparent than fused quartz for these purposes, but its birefringence introduces complications and design.

Quartz also has the property of rotating the plane of vibration of polarized light traveling along its axis. This property is associated with its left- or right-handed character. Sugar solutions have the same optical rotating power and quartz planes or wedges are employed as standards and optical devices used for analyzing sugar solutions by means of this rotary power. Many other organic chemicals that have asymmetric right- or left-handed molecules can be studied and assayed by this optical means.

The variation of this rotary power of quartz with wavelength or color of light makes it possible to construct monochromators capable of selecting light of a desired color from a white source with very large optical apertures.

Amorphous Silica

The amorphous form of silica also has mechanical, optical, thermal, and electrical properties, which make it very useful in hundreds of technical applications. Vitreous silica is made by three different processes. The earliest process, which is still used, consists simply of melting quartz by application of high temperature. The oxyhydrogen flame was the first source of heat for this process and is still used to melt fragments of rock crystal that are combined to form rods and other shapes of silica glass. However, electrical heat from graphite resistors is more commonly employed at present since there is less

S

trouble from volatilization of the silica. Large masses can be made by this technique and shaped into various useful forms although the very high temperature required for working silica glass makes this method of manufacture difficult and expensive.

To obtain a clear transparent product, crystal must be melted. If sand is used, the product is white and opaque because of the numerous air bubbles trapped in the very viscous glass. It is impossible to heat silica glass hot enough to drive out the bubbles or, in glass parlance, to "fine" it. However, the opaque "vitreous" made by fusing sand is very useful for chemical apparatus, when the low thermal expansion and insolubility of the silica glass play a role.

Recently, the Corning Glass Works developed a new process for making silica glass by hydrolysis of silicon tetrachloride in a flame. The resulting silica is deposited directly on a support in the form of transparent silica glass, which is more homogeneous and purer than the glass made by fusing quartz.

Large pieces can be made by this process and the unusual homogeneity of the product makes it especially useful for optical parts and for sonic delay lines where striations in the older fused quartz are detrimental. The sonic delay lines are polygons of the silica glass in which acoustic waves travel on a long path, being reflected at the numerous polygonal faces.

Finally, silica glass of 96% purity or better is made by an ingenious process invented by the Corning Glass Works. In this third process for making vitreous silica, an object is shaped first from a soft glass containing about 30% of borax and boric acid as fluxes. A suitable heat treatment causes a submicroscopic separation of two glass phases. One phase, which is composed chiefly of the fluxes, is then bleached from the glass in a hot, dilute nitric acid bath. If the composition and heat treatment are exactly right, the high silica phase is left as a porous "sponge" with the shape and size of the original soft glass article. This is carefully washed and dried and fired by heating to about 1200°C.

In the firing step, the porous silica sponge shrinks to a dense transparent object of glass containing 96% SiO₂ or more, which has the desirable properties of silica glass made by either of the other processes. The 4% of impurity in the glass made by this process consists chiefly of boric oxide. Because of its presence, this glass is appreciably softer than pure silica glass. For corresponding viscosities, the "Vycor" 96% silica glass requires about 100°C lower temperature.

Silica glass made by any of these processes has many uses because of its unique combination of good properties.

Fibers of silica glass have very high tensile strength and almost perfect elasticity. This makes them useful in constructing microbalances, electrometers, and similar instruments. Silica fiber in diameters as small as 0.000076 cm comes in random matted form or in rovings.

Because of its small thermal expansion, fused silica is very resistant to sudden temperature changes. It is also a very hard glass so that it may be used in the laboratory for crucibles and combustion tubes to much better advantage than ordinary glass. Vitreous silica makes possible the construction of thermometers operating up to 1000°C. The small thermal expansion and durability of fused silica have led to its use in fabrication of standards of length. Fused silica plates, ground to optical flatness, are used in interferometers for measurement of thermal expansion.

The fact that fused silica is an excellent insulator with little or no tendency to condense surface films of moisture makes it valuable in the construction of electrical apparatus. It has a very high dielectric strength and low dielectric loss.

Silica glass also has very good transmission for visible and ultraviolet light. This makes it useful for the construction of mercury lamps and other optical equipment. In the mercury lamps,

the strength and heat resistance of silica glass makes it possible to operate with high internal pressures, producing very high light intensities and great efficiency. The 96% silica glass made by the Vycor process may be fired in a reducing atmosphere or in vacuum to modify and improve its light-transmitting properties.

Silica glass is among the most chemically resistant of all glasses. This makes it particularly useful in the analytical laboratory where there is the added advantage that any contamination of contained solutions can only be by the one oxide, silica. Crucibles of fused silica glass may be used for pyrosulfate fusions. Condensers of fused silica are extremely useful for distilling acids (except hydrofluoric) and for preparation of an extremely pure water.

Another useful form of silica is obtained by dehydrating silicic acid. In this way, a porous "gel" is obtained that has an enormous surface area and is capable of adsorbing various gases and vapors, particularly water vapor. Silica gel is used in dehumidifiers to remove water vapor from the air. It is also used as a catalyst and as a support for other catalysts.

The porous 96% silica skeleton obtained in the Vycor process also has a very large surface and is useful as an adsorbent and drying agent. It has less capacity than silica gel, but better mechanical strength.

A very finely divided form of silica known as silica soot is obtained by hydrolizing silicon tetrachloride in a flame without heating the product hot enough to consolidate it in as a glass. This material is valuable as a thermal insulator and as a white filler for rubber and plastics.

Other Uses

The silica (actually ground silica) used in the pottery industry is called flint. The addition of flint affects warpage very little.

In ceramic bodies, potters' flint or pulverized quartz or sand is the constituent that reduces drying and burning shrinkage and assists promotion of refractoriness. Flint has an important bearing on the resistance of bodies to thermal and mechanical shock, because of the volume changes that accompany crystal transformation. In the unburned body, it lowers plasticity and workability, lowers shrinkage, and hastens drying. A coarse crystalline form of quartz, called macrocrystalline quartz, is more often used for potters' flint than the cryptocrystalline form.

Silica is used in all glazes as the chief, and often the only, acid radical (RO₂ group). It may be adjusted to regulate the melting temperature of the glaze. In common glazes, the ratio of silica to bases (RO group) is never less than 1:1 nor more than 3:1. By varying the relative proportions of the RO group and balancing the group against any desired silica content, the maturing temperature of a glaze may be quite closely controlled. In other words, the fusibility of the glazes used in the presence of equal proportions of fluxes depends on their relative silica contents.

In porcelain enamels, it may be taken as a general rule that, other things remaining constant, the higher the percentage of silica, the higher will be the melting point of the enamel and the greater its acid resistance. Silica has a low coefficient of expansion and increasing it in an enamel lowers the coefficient of expansion of that enamel. One method of regulating an enamel coating is to increase the silica content when the enamel is inclined to split off in cooling. Silica is a form of flint or quartz is used in both ground-coat and cover-coat enamels, and it has the same effect in either type.

The temperature required for melting an enamel is materially affected by the fineness of the silica. Cryolite, antimony, and tin oxide give their maximum value as pacifiers with minimum heat treatment in the smelter. The form and fineness of the silica should, therefore, be carefully watched and allowed for in compounding

the batch. All forms of silica may be used with good results, but experience has shown that, in the same enamel, a smaller quantity of sand than of powdered quartz is necessary. Similarly, less sand than flint should be used, but the difference in this case is less than in the former. High SiO_2 tends to harden the enamel. The lower limit established in the usual run of enamels is 1:1 equivalents.

In the manufacture of semiconductors, monolithic circuits, and integral circuits for the electronics industry, the use of fused quartz is widespread for plumbing and diffusion furnace muffles. The need to prevent product contamination makes this choice mandatory.

Irish Refrasil is 98% silica and has a green color. It is used for ablative protective coatings. It resists temperatures to 1588°C . Silica flour, made by grinding sand, is used in paints, as a facing for sand molds, and for making flooring blocks. Silver bond silica is water-floated silica flour of 98.5% SiO_2 , ground to 325 mesh. In zinc and lead paints, it gives a hard surface. Pulverized silica, made from crushed quartz, is used to replace tripoli as an abrasive. Ultrafine silica, a white powder having spherical particles of 4–25 μm , is made by burning silicon tetrachloride. It is used in rubber compounding, as a grease thickener, and as a flattening agent in paints. An example of this material is *Aerosil*.

A polymer-impregnated silica, *Polysil*, has twice the dielectric strength of porcelain as well as better strength. It is also cheaper to make, and its composition can be tailored to meet specific environmental and operating conditions.

Silica aerogel is a fine, white, semitransparent silica powder; its grains have a honeycomb structure, getting extreme lightness. It weighs 40 kg/m^3 and is used as an insulating material in the walls of refrigerators, as a filler in molding plastics, as a flattening agent in paints, as a bodying agent in printing inks, and as a reinforcement for rubber. It is produced by treating sand with caustic soda to form sodium silicate, and then treating with sulfuric acid to form a jelly-like material called *silica gel*, which is washed and ground to a fine dry powder. It is also called *synthetic silica*.

Silicon monoxide, SiO , does not occur naturally but is made by reducing silica with carbon in the electric furnace and condensing the vapor out of contact with the air. It is lighter than silica, having a specific gravity of 2.24, and is less soluble in acid. It is brown powder valued as a pigment for oil painting, as it takes up a higher percentage of oil than ochres or red lead. It combines chemically with the oil. Fumed silica is a fine translucent powder of the simple amorphous silica formula made by calcining ethyl silicate. It is used instead of carbon black in rubber compounding to make light-colored products, and to coagulate oil slicks on water so that they can be burned off. It is often called white carbon, but the “white carbon black” called *Cab-O-Sil*, used for rubber, is a silica powder made from silica and tetrachloride. *Cab-O-Sil EH5*, a fumed colloidal form, is used as a thickener in resin coatings. The thermal expansion of amorphous fused silica is only about 1/8 that of alumina. Refractory ceramic parts made from it can be heated to 1093°C and cooled rapidly to subzero temperatures without fracture.

Silica Flour

A sand additive, containing about 99.5% silica, commonly produced by pulverizing quartz sand and large ball mills to a mesh size of 80–325.

Silica Gel

A precipitated colloidal mass or gel of indefinitely hydrated silica; also the dried or activated product of the same. Useful as a desiccant, scavenger, and catalyst substrate.

Silica Minerals

Silica occurs naturally in at least nine different varieties (polymorphs), which include tridymite (high-, middle-, and low-temperature forms), cristobalite (high- and low-temperature forms), coesite, and stishovite, in addition to high (β) and low (α) quartz. These forms have distinctive crystallography and optical characteristics.

The transformation between the various forms are of two types. Displacive transformations, such as inversions between-temperature (β) and low-temperature (α) forms, result in a displacement or change in bond direction but involve no breakage of existing bonds between silicon and oxygen atoms. These transformations take place rapidly over a small temperature interval and are reversible. Reconstructive transformations, in contrast, involve disruption of existing bonds and subsequent formation of new ones. These changes are sluggish, thereby permitting a species to exist metastably outside its defined pressure-temperature stability field. Two examples of reconstructive transformations are $\leq$ quartz and $\leq$ stishovite.

Silicate-Type Inclusions

Inclusions composed essentially of silicate glass, normally plastic at forging and hot-rolling temperatures, that appear in steel in the wrought condition as small elongated inclusions usually dark in color under reflected light as normally observed.

Silicides

Silicides are a group of substances, usually compounds, comprising silicon in combination with one or more metallic elements. These hard, crystalline materials are closely related to intermetallic compounds and have, therefore, many of the physical and chemical characteristics and some of the mechanical properties of metals.

Silicides are not natural products. They received but little attention prior to the development of the electrical furnace, which provided the first practical means of attaining and controlling the high temperatures generally required in their preparation.

Composition

Although a majority of the metals react with silicon, many of the resulting silicides do not have the properties usually required in engineering materials. The silicides that appear most promising for practical utilization in engineering and structural applications are, with few exceptions, limited to those of the refractory, or high melting metals of groups IV, V, and VI of the periodic table. Included in this category are the silicides of titanium, zirconium, hafnium, vanadium, columbium, tantalum, chromium, molybdenum, and tungsten.

Silicides can be prepared by direct synthesis from the elements, by reduction of silica or silica and halogenides and the appropriate metal oxide or halogenide with silicon, carbon, aluminum, magnesium, hydrogen, etc., and by electrolysis of molten compounds. They are also obtained as by-products in many metallurgical processes. High-purity silicides of stoichiometric composition are difficult to prepare.

The chemical composition of silicides cannot, in general, be predicted from a consideration of the customary valences of the elements. The zirconium–silicon system, for example, is reported to include the compounds Zr_4Si , Zr_2Si , Zr_3Si_2 , Zr_6Si_5 , ZrSi , and ZrSi_2 . The disilicide composition (MSi_2) occurs in all

S

of the refractory metal–silicon systems and probably will prove the most important, particularly in those applications requiring high-temperature stability.

General Properties

Silicides resemble silicon in their chemical properties with the degree of similarity roughly proportional to the silicon content. At normal temperatures, the refractory metal disilicides are inert to most ordinary chemical reagents. The compounds are not thermodynamically stable in the presence of oxygen and in the finely pulverized state they oxidize readily. However, in massive form, they are oxidation resistant because of the formation of a protective surface layer of silica. Bodies of MoSi_2 and WSi_2 are highly resistant to oxidation even at temperatures approaching their melting points.

The physical and mechanical characteristics of silicides are, to a large extent, determined by the properties of the component metal. The refractory metal silicides have highly crystalline structures and moderate densities. Their melting points are intermediate to relatively high. They have low electrical resistance, high thermal conductivity, and fair thermal shock resistance. They have high hardness, high compressive strength, and moderate tensile strength at both room and elevated temperatures. The elevated temperature stress-rupture and creep properties are good. Brittleness at low impact resistance are the most serious disadvantages of these materials.

Excellent oxidation resistance has prompted detailed studies of molybdenum disilicide. Quantitative information on the properties of most silicides has been developed within the past two decades.

Fabrication

The general methods used for consolidating powders can be applied to the silicides. High-density parts are obtained by cold pressing and sintering and also by hot pressing. Slip casting and extrusion are convenient methods for preparing certain shapes and sizes. Casting in the molten state is difficult due to the partial decomposition of silicides at their melting points. Silicide coatings can be prepared by vapor deposition techniques. Dense, fully sintered silicide parts are extremely difficult to work. They can be cut using silicon carbide or diamond wheels. Grinding has shown some promise but it is a slow process. “Green” or presintered compacts can, however, be shaped by conventional methods.

Availability

Although the availability of silicides is gradually increasing, the varieties, quantities, and shapes are limited. Molybdenum disulfide is commercially available in powder form and as furnace heating elements, and certain shapes and sizes have been produced on a custom basis. Some of the other compositions can be obtained on special order. The small market that has developed for MoSi_2 can be expected to stimulate general interest in the silicides and to foster their commercial development and production.

The practical utilization of silicides, with few exceptions, notably MoSi_2 furnace heating elements, has been implemented. Molybdenum disulfide is a structural material for gas turbine and missile components, which do not require high impact and thermal shock resistance. Igniter elements, thermocouple shields, gas probes, and nozzles are other potential applications. The high hardness of these materials has found usage in metalworking dies and tooling.

Silicide coatings, prepared by vapor-phase deposition, afford excellent oxidation protection to molybdenum and tungsten.

This method of providing oxidation resistance is versatile because fabrication can be completed before the coating is applied. Similar coatings can be produced on other materials such as graphite by using silicide powders. Silicide coatings are commercially available and are a major item in the present market for silicide products.

Silicon

A metallic element (symbol Si), silicon is used chiefly in its combined state and is the most abundant solid element in the Earth's crust (28%).

The metal has been prepared by reducing the tetrachloride by hydrogen using a hot filament, or by aluminum, magnesium, or zinc. The fluoride or alkali fluorosilicates have been reduced with alkali metals or aluminum. Silica can be converted to metal by reduction in the electric furnace with carbon, silica carbide, aluminum, or magnesium. The element has also been produced by the fusion electrolysis of silica in molten alkali oxide–sodium chloride–aluminum chloride baths. Extremely pure metal has been made by the treatment of silanes with hydrogen.

It is a gray-white, brittle, metallic-appearing element, not readily attacked by acids except by a mixture of HF and HNO_3 . It is soluble in hot NaOH or KOH and is prepared in the pure crystalline form by reduction of fractionally distilled SiCl_4 .

Silica combines with many elements including boron, carbon, titanium, and zirconium in the electric furnace. It readily dissolves in molten magnesium, copper, iron, and nickel to form silicides. Most oxides are reduced by silicon at high temperatures.

Fabrication

Silicon can be cast by melting in a vacuum furnace and cooling in vacuum by withdrawing the element from the heated zone. Single-crystal ingots have been prepared by drawing from the melt and by the “floating zone” technique. It is claimed that silicon exhibits some workability above 1000°C , but at room temperature it is very brittle. Metals can be coated with a silicon-rich layer by reducing the tetrachloride with hydrogen on the hot metal surface.

Types

In very pure form, silicon is an intrinsic semiconductor, although the extent of its semiconduction is greatly increased by the introduction of minute amounts of impurities.

Pure silicon metal is used in transistors, rectifiers, and electronic devices. It is a semiconductor and is superior to germanium for transistors as it will withstand temperatures to 149°C and will carry more power. Rectifiers made with silicon instead of selenium can be smaller and will withstand higher temperatures. Its melting point when pure is about 1434°C , but it readily dissolves in molten metals. It is never found free in nature but, when combined with oxygen, it forms silica, SiO_2 , one of the most common substances on Earth. Silicon can be obtained in three modifications.

Form

Amorphous silicon is a brown-colored powder with a specific gravity of 2.35. It is fusible and dissolves in molten metals. When heated in the air, it burns to form silica. Graphitoidal silicon consists of black glistening spangles and is not easily oxidized and not attacked by the common acids, but is soluble in alkalis. Crystalline silicon is obtained in dark, steel-gray globules of crystals or six-sided

pyramids of specific gravity 2.4. It is less reactive than the amorphous form, but is attacked by boiling water. All these forms are obtainable by chemical reduction. Silicon is an important constituent of commercial metals. Molding sands are largely silica, and silicon carbides are used as abrasives. Commercial silicon is sold in the graphitoid flake form, or as ferrosilicon, and silicon-copper. The latter forms are employed for adding silicon to iron and steels. Commercial refined silicon contains 97% pure silicon and less than 1% iron. It is used for adding silicon to aluminum alloys and for fluxing copper alloys. High-purity silicon metal, 99.95% pure, made in an arc furnace, is too expensive for common uses, which is employed for electronic devices and in making silicones. For electronic use, silicon must have extremely high purity, and the pure metal is a nonconductor with a resistivity of 300,000 Ω cm. For semiconductor use, it is "doped" with other atoms yielding electron activity for conducting current. Epitaxial silicon is a higher purified silicon doped with exact amounts of impurities added to the crystal to give the desired electronic properties.

Principal Compounds

Silicate is reported to form compounds with 64 of the 96 stable elements, and it probably forms silicides with 18 other elements. Besides the metal silicides, used in large quantities and metallurgy, silicon forms useful and important compounds with hydrogen, carbon, the halogen elements, nitrogen, oxygen, and sulfur. In addition, useful organosilicon derivatives have been prepared.

Hydrides

The hydrides of silica are named silanes; the compound SiH_4 is called monosilane, Si_2H_6 disilane, Si_3H_8 trisilane, and so on. Compounds in which oxygen atoms alternate with silicon atoms in the principal part of the structure are called siloxanes, and those with nitrogen between silicon atoms are called silazanes. All other covalent compounds of silicon are considered for the purpose of nomenclature to be derived from these silanes, and modified silanes are named according to substituent groups and their placement along the principal silicon-containing chain or ring.

Use

Because of its inherent brittleness, there are no engineering applications of silicon. The chief use of highly purified metal is as a semiconductor in transistors, rectifiers, and solar cells. It may be fired with ceramic materials to form heat-resistant articles. Silicon can serve as an autoxidation catalyst and as an element in photocells. Mirrors for dental use are formed with a reflecting surface of silicon. The metal is also employed to prepare silicides and alloys, and to coat various materials. In commercial quantities, it is also used as a starting material for the synthesis of silicones.

By far the largest use of silicon is as compounds in the ceramic industry. It is also employed as an alloying element in ferrous metals and is the basis of the family of chemicals known as silicones.

An important application of silicon is in the electronics industry where it has been widely employed in the manufacture of crystal rectifiers and integrated circuits. Sufficiently pure silicon has been produced by carefully controlled zone refining and crystal growth to make possible its use as transistors. Since the energy gap of silicon is 1.1 eV, compared with 0.75 eV for germanium, silicon transistors may be operated at higher temperatures and power levels than those made of germanium.

Silicon Bronze

Silicon bronze is a family of wrought copper-base alloys (C64700–C66100) and one cast copper alloy (C87200), the wrought alloys containing from 0.4% to 0.8% silicon (C64700) to 2.8% to 4.0% silicon (C65600), and the cast alloy 1.0% to 5.0%, along with other elements, usually lead, iron, and zinc. Other alloying elements may include manganese, aluminum, tin, nickel, chromium, and phosphorus. The most well-known alloys are probably silicon bronze C65100, or low-silicon bronze B, and silicon bronze C65500, or high-silicon bronze A, as they were formally called. As these names imply, they differ mainly in silicon content: 0.8%–2.0% and 2.8%–3.8%, respectively, although the latter alloy also may contain as much as 0.6% nickel. C87200 contains at least 89% copper, 1.5% silicon, and as much as 5% zinc, 2.5% iron, 1.5% aluminum, 1.5% manganese, 1% tin, and 0.5% lead. Regardless of alloying ingredients, copper content is typically 90% or greater.

Both of the common wrought alloys are quite ductile in the annealed condition, C65500 somewhat more ductile than C65100, and both can be appreciably strengthened by cold working. Annealed, tensile yield strengths are on the order of 103–172 MPa depending on mill form, with ultimate tensile strengths to about 414 MPa and elongations of 50%–60%. Cold working can increase yield strength to as much as 483 MPa. Electrical conductivity is 12% for C65100 and 7% for C65500 relative to copper, and thermal conductivity is 57 and 36 W/(m K), respectively. The alloys are used for hydraulic-fluid lines in aircraft, heat-exchanger tubing, marine hardware, bearing plates, and various fasteners.

Silicon bronze C87200 is suitable for centrifugal, investment, and sand, plaster, and permanent-mold castings. As sand cast, typical tensile properties are 379 MPa ultimate strength, 172 MPa yield strength, and 30% elongation. Hardness is Brinell 85, electrical conductivity 6%, and, relative to free-cutting brass, machinability is 40%. Uses include pump and valve parts, and marine fittings and bearings.

Silicon Carbide

The reduction of silica with excess carbon under appropriate conditions give silicon carbide (SiC), which crystallizes in a number of forms but is best known in the cubic-diamond form with spacing α_0 of 0.435 nm (compared with 0.356 nm for diamond). In the pure form, silicon carbide is green (α -hexagonal) or yellow (β -cubic), but the commercial product is black and has a bluish or greenish iridescence. The carbide is not easily oxidized by air except above 1000°C, and retains its physical strength up to this temperature. For these reasons, it is a favorite structural refractory material for the ceramic arts. It also is extremely hard, with a Mohs hardness in excess of 9, and so has found wide application as an abrasive.

Silicon carbide does not melt without decomposition at atmospheric pressure, but does not melt at 2830°C at 3.5 MPa.

Forms

β -SiC (cubic) forms at 1400°C–1800°C and α -SiC (hexagonal) forms at temperatures > 1800°C.

SiC is used as an abrasive as loose powder, coated abrasive cloth and paper, wheels, and hones. It will withstand temperatures to its decomposing point of 2301°C and is valued as a refractory. It retains its strength at high temperatures, has a low thermal expansion, and its heat conductivity is 10 times that of fireclay. Silicon carbide is made by fusing sand and coke at a temperature above 2204°C.

S

Unlike aluminum oxide, the crystals of silicon carbide are large, and they are crushed to make the small grains used as abrasives. They are harder than aluminum oxide, and because they fracture less easily, they are more suited for grinding hard cast irons and ceramics. The standard grain sizes are usually from 100 to 1000 mesh. The crystalline powder in grain sizes from 60 to 240 mesh is also used in lightning arrestors. *Carborundum*, *Crystolon*, and *Carbolon* are trade names for silicon carbide.

Types

Three main types are produced commercially. Green SiC is an entirely new batch composition made from a sand and coke mixture, and is the highest purity of the three. Green is typically used for heating elements. Black SiC contains some free silicon and carbon and is less pure. A common use is as bonded SiC, and is not very pure. It is typically used as a steel additive.

Fabrication and Properties

Silicon carbide is manufactured in many complex bonded shapes, which are utilized for super-refractory purposes such as setter tile and kiln furniture, muffles, retorts and condensers, skid rails, hot cyclone liners, rocket nozzles and combustion chambers, and mechanical shaft seals. It is also used for erosion- and corrosion-resistant uses such as check valves, orifices, slag blocks, aluminum die casting machine parts, and sludge burner orifices. Electrical uses of SiC include lightning arrestors, heating elements, and nonlinear resistors.

Silicon carbide refractories are classified on the basis of the bonds used. Associated-type bonds are oxide or silica, clay, silicon oxynitride, and silicon nitride, as well as self-bonded.

A process for joining high-temperature-resistant silicon carbide structural parts that have customized thermomechanical properties has been developed, and the materials include SiC-based ceramics and composites reinforced by different fibers.

The method begins with the application of a carbonaceous mixture to the joints. The mixture is cured at a temperature between 90°C and 110°C. The joints are then locally infiltrated with molten silicon or with alloys of silicon and refractory metals. The molten metal reacts with the carbon in the joint to form silicon carbide and quantities of silicon and refractory disilicide phases that can be tailored by choosing the appropriate reactants.

In mechanical tests, the joints were found to retain their strength at temperatures from ambient to 1370°C. The technique can also be used in the repair of such parts.

Uses and Applications

SiC is used in the manufacture of grinding wheels and coated abrasives. Large tonnages are used in cutting granite with wire saws and as a metallurgical additive in the foundry and steel industries.

Other uses are in the refractory and structural ceramic industries. As an abrasive, silicon carbide is best used either on very hard materials, such as cemented carbide, granite, and glass, or on soft materials, such as wood, leather, plastics, and rubber.

Refrax Silicon Carbide and KT

The first material is bonded with silicon nitride. It is used for hot-spray nozzles, heat-resistant parts, and for lining electrolytic cells for smelting aluminum. Silicon carbide KT is molded without a

binder. It has 96.5% SiC with about 2.5% silica. The specific gravity is about 3.1, and it is impermeable to gases. It is made in rods, tubes, and molded shapes.

Silicon Carbide Foam

This is a lightweight material made of self-bonded silicon carbide foamed into shapes. It is inert to hot chemicals and can be machined.

Silicon Carbide Crystals

These are used for semiconductors at temperatures above 343°C. As the cathode of electronic tubes instead of a hot-wire cathode, the crystals take less power and need no warm-up.

Silicon Carbide Fibers

SiC fiber is one of the most important fibers for high-temperature use. It has high strength and modulus and will withstand temperatures even under oxidizing conditions up to 1800°C, although the fibers show some deterioration in tensile strength and modulus properties at temperatures above 1200°C. It has advantages over carbon fibers for some uses, having greater resistance to oxidation at high temperatures, superior compressive strength, and greater electrical resistance.

There are two forms of SiC fibers. One consists of a pyrolytic deposit (chemical vapor deposition) of SiC on an electrically conductive usually carbon, continuous filament. Fiber diameter is about 140 μm . This technology has been used to make filaments with both graded and layered structures, including surface layers of carbon, which provide a toughness-enhancing parting layer in composites with a brittle matrix (e.g., silicon nitride).

The other forms of filamentary SiC are fibers that are extruded from sinterable SiC powder and allowed to sinter during free fall from the extruder. Fibers produced to date are 0.13–0.25 mm in diameter.

There are two commercial processes for making continuous silicon carbide fibers: (1) by coating silicon carbide on either a tungsten or a carbon filament by vapor deposition to produce a large filament (100–150 μm in diameter), or (2) by melt spinning an organic polymer containing silicon atoms as a precursor fiber followed by heating at an elevated temperature to produce a small filament (10–30 μm in diameter). Fibers from the two processes differ considerably from each other but both are used commercially.

Improved composites of SiC fibers in Si/SiC matrices have been invented for use in applications in which there are requirements for materials that can resist oxidation at high temperatures in the presence of air and steam. Such applications are likely to include advanced aircraft engines and gas turbines.

The need for improved composites arises: Although both the matrix and fiber components of older SiC/(Si/SiC) composites generally exhibit acceptably high resistance to oxidation, these composites become increasingly vulnerable to oxidation and consequent embrittlement whenever mechanical or thermomechanical loads become large enough to crack the matrices. Even the narrowest cracks become pathways for the diffusion of oxygen.

Typically, to impart toughness to an SiC/(Si/SiC) composite, the SiC fibers are coated with a material that yields a high stress to allow some slippage between the fibers and matrix. If oxygen infiltrates through the cracks to the fiber coatings, then, at high temperature, the oxygen reacts with the coatings (and eventually with the fibers), causing undesired local bonding between fibers in the matrix and consequent loss of toughness.

The improved composites incorporate matrix additives and fiber coatings that retard the infiltration of oxygen by reacting with oxygen in such a way as to seal cracks and fiber/matrix interfaces at high temperatures. These matrix additives and coating materials contain glass-forming elements—for example, boron and germanium.

Boron is particularly suitable for use in fiber coatings because it can react with oxygen to form boron oxide, which can, in turn, interact with the silica formed by oxidation of the matrix and fiber materials to produce borosilicate glasses. Boron and SiB_6 may prove to be the coating materials of choice because they do not introduce any elements beyond those needed to form borosilicate glasses.

One way to fabricate an SiC/(Si/SiC) composite object is to first make a preform of silicon carbide fibers interspersed with a mixture of silicon carbide and carbon particles, then infiltrate the preform with molten silicon. Boron can be incorporated by chemical vapor deposition onto the fibers prior to making the preform.

Boron and germanium can be incorporated into the matrix by adding these elements to either the matrix or the molten silicon infiltrant. Inasmuch as the solubility of boron and silicon is limited, it may be necessary to add the boron via the preform in a typical case.

Silicon Carbide Platelets

Single crystals of α -phase hexagonal crystal structure and four size ranges currently are produced: -100 , $+200$ mesh (100–300 μm in diameter, 5–15 μm thick); -200 , $+325$ mesh (50–150 μm in diameter, 1–10 μm thick); $+325$ mesh (5–70 mm in diameter, 0.5–5 mm thick); and -400 mesh (3–30 μm in diameter, 0.5–3 μm thick). The finest size is a research product, and additional development work has been conducted to produce an even smaller diameter platelet in the 0.5 μm range, which would be an ideal reinforcement material for ceramic-matrix composites.

In addition to reinforcing ceramics, silicon carbide platelets also are used to increase the strength, wear resistance, and thermal shock performance of aluminum matrices, and to enhance the properties of polymeric matrices. Because platelets are very free flowing, they can be processed in the same manner as particulates.

Silicon Carbide Whiskers

Whiskers as small as 7 μm in diameter can be made by a number of different processes. Although these whiskers have the disadvantage in some applications of not being in continuous filament form, it can be made with higher tensile strength and modulus values than continuous silicon carbide filaments.

Silicon carbide whiskers are single crystals of either α - or β -phase crystal structure. The SiC whiskers tend to exhibit a hexagonal, triangular, or rounded cross-section and may contain stacking faults.

SiC whiskers can be fabricated by the reaction of silicon and carbon to form a gaseous species that can be transported and reacted in the vapor phase. This type of formation is referred to as a vapor-solid reaction.

The reactions occur at temperatures greater than 1400°C and in an inert or nonoxidizing atmosphere. In addition, a catalyst is added to assure the formation of whiskers rather than particulate during the reaction.

Although SiC whiskers can be coated with several different materials, such as carbon, to enhance their performance, the as-produced SiC whiskers generally contain a 5–30 SiO_2 coating, which forms during synthesis.

SiC whiskers are added to a variety of matrices to increase the toughness and high-temperature strength of these materials. The elastic modulus for SiC whiskers is 400–500 GPa and the tensile strength ranges from 1 to 5 GPa. A variety of ceramic matrices, such as aluminum oxide, silicon nitride, molybdenum disilicide, aluminum nitride, mullite, cordierite, and glass ceramics, are combined with SiC whiskers to increase the overall mechanical properties of the resulting composite. For example, the wear resistance, toughness, and thermal shock of aluminum oxide is increased by the addition of SiC whiskers. The resulting composite has been used for such applications as high-performance cutting tool inserts. The addition of SiC whiskers to an alumina matrix can double the fracture toughness of the resulting composite, depending on whisker content and processing conditions.

SiC whiskers also can be combined with metals to increase the high-temperature strength of a material as well as provide a comparable substitution for heavier traditional materials, such as steel. Metal-matrix composites (MMCs) are being tested for such applications as piston ring grooves, cylinder block liners, brake calipers, and aerospace components. MMCs can be fabricated by infiltrating an SiC whisker preform with aluminum or by the addition of SiC whiskers to molten aluminum.

Polymer-matrix composites combine the strength and impact resistance of polymers with the thermal conductivity, fatigue, and wear resistance of the whiskers. Whisker-reinforced polymers have strong potential to replace traditional plastics in automotive, aerospace, and recreational applications.

Silicon Cast Iron

This is an acid-resistant cast iron containing a high percentage of silicon. When the amount of silicon and cast iron is above 10%, there is a notable increase in corrosion and acid resistance. The acid resistance is obtained from the compound Fe_3Si , which contains 14.5% silicon. The usual amount of silicon in acid-resistant castings is from 12% to 15%. The alloy casts well but is hard and cannot be machined. These castings usually contain 0.75%–0.85% carbon.

A 14%–14.5% silicon iron has a silvery-white structure and is resistant to hot sulfuric acid, nitric acid, and organic acids. Silicon irons are also very wear resistant and are valued for pump parts and for parts for chemical machinery.

Silicon Copper

An alloy of silicon and copper used for adding silicon to copper, brass, or bronze, silicon copper is also employed as a deoxidizer of copper and for making hard copper. Silicon alloys in almost any proportion with copper and is the best commercial partner of copper. A 50-50 alloy of silicon and copper is hard and extremely brittle and black in color. A 10% silicon and 90% copper alloy is as brittle as glass; in this proportion, silicon copper is used for making the addition to molten copper to produce hard, sound copper alloy castings of high strength. The resulting alloy is easy to cast in the foundry and does not dross. Silicate-copper grades in 5%, 10%, 15%, and 20% silicon are also marketed. A 10% silicon-copper melts at 816°C; a 20% alloy melts at 623°C.

Silicon Halides

Silicate tetrachloride, SiCl_4 , is perhaps the best-known monomeric covalent compound of silicon. It is readily available commercially. It can be prepared by chlorinating elementary silicon, or by the action

S

of chlorine on a mixture of silica with finely divided carbon, or by the chlorination of silicon carbide. It is a volatile liquid that fumes in moist air and hydrolyzes rapidly to silica and hydrochloric acid.

Pure silica with very high surface area, produced by this method, is used as a reinforcing filler (white carbon black) in silicone rubber and as a thickening agent in organic solutions. Silicate tetrachloride reacts readily with alcohols and glycols, for example, to form the corresponding ethers, which may also be considered to be esters of silicic acid.

Silicon Manganese

An alloy employed for adding manganese to steel, and also as a deoxidizer and scavenger of steel, silicon manganese usually contains 65%–70% manganese and 12%–25% silicon. It is graded according to the amount of carbon, generally 1%, 2%, and 2.5%. For making steels low in carbon and high in manganese, silicomanganese is more suitable than ferromanganese. A reverse alloy, called manganese–silicon, contains 73%–78% silicon and 20%–25% manganese, with 1.5% max iron and 0.25% max carbon. It is used for adding manganese and silicon to metals without the addition of iron. Still another alloy is called ferromanganese–silicon, containing 20%–25% manganese, about 50% silicon, and 25%–30% iron, with only about 0.50% or less carbon. This alloy has a low melting point, giving ready solubility in the metal.

Silicon Nitride

Silicon nitride (Si_3N_4) disassociates in air at 1800°C and at 1850°C under 1 atm N_2 . There are two crystal structures: α (1400°C) and β (1400°C–1800°C), both hexagonal. Its hardness is approximately 2200 on the Knoop K100 scale, and it exhibits excellent corrosion and oxidation resistance over a wide temperature range. Typical applications are molten-metal-contacting parts, wear surfaces, special electrical insulator components, and metal forming dies. It is under evaluation for gas turbines and heat engine components as well as antifriction bearing members.

Processing

Pure silicon nitride powders are produced by several processes, including direct nitridation of silicon, carbothermal reduction— $\text{C} + \text{SiO}_2 + \text{N}_2$ yields Si_3N_4 (gas atmosphere)—and chemical vapor deposition— $3\text{SiH}_4 + 4\text{NH}_3$ yields $\text{Si}_3\text{N}_4 + 12\text{H}_2$. Reacting SiO_2 with ammonia or silanes with ammonia will also produce silicon nitride powders. It is found that the highest purity powders come from gas-phase reactions.

Types

Sinterable/Hot Pressed/Hot Isostatically Pressed Silicon Nitride

These types are SSN, HPSN, and HIPSN, respectively. They are used mainly in the higher performance applications. Powdered additives, known as sintering aids, are blended with the pure Si_3N_4 powder and allow densification to proceed via the liquid state. Pore-free bodies can be so produced by sintering or hot pressing. Of course, the properties of the material and dense pieces are dependent on the chemical nature of the sintering aids employed.

Sinterable silicon nitrides are a more recent innovation and allow more flexibility in shape fabrication than does HPSN. Highly complex shapes can be die-pressed or isostatically pressed. Densification

can be performed by either sintering or hot isostatic pressing (HIP). Properties of the dense piece are dependent on the additives, but in general the strength below 1400°C, as well as oxidation resistance of HPSN and SSN, far exceeds those properties for reaction-bonded silicon nitride (RBSN).

Reaction-Bonded Silicon Nitride

More common today is RBSN. Silicon powder is pressed, extruded, or cast into shape, then carefully nitrided in a N_2 atmosphere at 1100°C–1400°C, so as to prevent an exothermic reaction, which might melt the pure silicon.

The properties of RBSN are usually lower than those of HPSN or SSN, due mainly to the fact that bodies fabricated in this manner only reach 85% of the theoretical density of silicon nitride and no secondary phase between grains is present.

Silicon Nitride Fibers

Si_3N_4 fibers have been prepared by reaction between silicon oxide and nitrogen in the presence of a reducing agent in an electrical resistance furnace at 1400°C. Silicon nitride short fibers are used in composites for specialty electrical parts, and aircraft parts, and radomes (microwave windows). Silicon nitride whiskers have also been grown as a result of the chemical reaction between nitrogen and a mixture of silicon and silica.

Silicon Oxides

Silicon dioxide is perhaps best known as one of its crystalline modifications known as quartz, colorless crystals of which are also known as rhinestones and Glens Falls diamonds. Purple or lavender-colored quartz is called amethyst, the pink variety is rose quartz, and the yellow type is citrine.

Because rock crystal has been collected and admired for thousands of years, large and perfectly formed natural crystals of quartz are now very rare. With the growth of radio broadcasting and the electronics industry, piezoelectric crystals cut from perfect specimens of quartz have been used in increasing quantities, to the point of scarcity of natural crystals. As the supply diminished, considerable effort was devoted to the problem of growing crystals of quartz by artificial means. Some success has been achieved by growing the crystals hydrothermally from a solution of silica glass in water containing an alkali or a fluoride.

A number of natural noncrystalline varieties of silicon dioxide are also known, such as the hydrated silica known as opal and the dense unhydrated variety known as flint. Onyx and agate represent still other semiprecious forms.

Silicon Steel

All grades of steel contain some silicon and most of them contain 0.10% to 0.35% as a residual of the silicon used as a deoxidizer. But 3% to 5% silicon is sometimes added to increase the magnetic permeability, and larger amounts are added to obtain wear-resisting or acid-resisting properties. Silicon deoxidizes steel, and up to 1.75% increases the elastic limit and impact resistance without loss of ductility. Silicon steels within this range are used for structural purposes and for springs, giving a tensile strength of about 517 MPa and 25% elongation.

The structural silicon steels are ordinarily silicon–manganese steel, with the manganese above 0.50%. Low-carbon steels used as structural steels are made by careful control of carbon, manganese, and silicon and with special mill heat treatment.

The value of silicon steel as a transformer steel occurs where silicon increases the electrical resistivity and also decreases the hysteresis loss, making silicon steel valuable for magnetic circuits where alternating current is used.

Silicone (SI) Resins

Silicone resins are synthetic materials capable of cross-linking or polymerizing to form films, coatings, or molded shapes with outstanding resistance to high temperatures.

They are a group of resin-like materials in which silicon takes the place of the carbon of the organic synthetic resins. Silicon is quadrivalent like carbon. But, while the carbon also has a valence of 2, silicon has only one valence of 4, and the angles of molecular formation are different. The two elements also differ in electronegativity, and silicon is an amphoteric element, with both acid and basic properties. The molecular formation of the silicones varies from that of the common plastics, and they are designated as inorganic plastics as distinct from the organic plastics made with carbon.

In the long-chain organic synthetic resins, the carbon atoms repeat themselves, attaching on two sides to other carbon atoms, while in the silicones the silicon atom alternates with an oxygen atom so that the silicon atoms are not tied to each other. The simple silane formed by silicon and hydrogen corresponding to methane, CH_4 , is also a gas, as is methane, and has the formula SiH_4 . But, in general, the silicones do not have the SiH radicals, but contain CH radicals as in the organic plastics.

Composition

Silicones are made by first reducing quartz rock (SiO_2) to elemental silicon in an electric furnace, then preparing organochlorosilane monomers (RSiCl_3 , R_2SiCl_2 , R_3SiCl) from the silicon by one of several different methods. The monomers are then hydrolyzed into cross-linked polymers (resins) whose thermal stability is based on the same silicon-oxygen-silicon bonds found in quartz and glass. The properties of these resins will depend on the amount of cross-linking and on the type of organic groups (**R**) included in the original monomer. Methyl, vinyl, and phenyl groups are among those used in making silicone resins.

Properties

Silicone resins have, in general, more heat resistance than organic resins, have higher dielectric strength, and are highly water resistant. Like organic plastics, they can be compounded with plasticizers, fillers, and pigments. They are usually cured by heat. Because of the quartzlike structure, molded parts have exceptional thermal stability. Their maximum continuous-use service temperature is about 260°C . Special grades exceed this and go as high as 371°C – 482°C . Their heat-deflection temperature for 1.8 MPa is 482°C . Their moisture absorption is low, and resistance to petroleum products and acids is good. Nonreinforced silicones have only moderate tensile and impact strength, but fillers and reinforcements provide substantial improvement. Because silicones are high in cost, they are premium plastics and are generally limited to critical or high-performance products such as high-temperature components in the aircraft, aerospace, and electronics fields.

Common characteristics shared by most silicone resins are outstanding thermal stability, water repellency, general inertness, and

electrical insulating properties. These properties, among others, have resulted in the use of silicone resins in the following fields:

1. Laminating (reinforced plastics), molding, foaming, and potting resins
2. Impregnating cloth coating, and wire varnishes for Class II (high-performance) electric motors and generators
3. Protective coating resins
4. Water repellents for textiles, leather, and masonry
5. Release agents for baking pans

Laminating Resins

Laminates made from silicone resin and glass cloth are lightweight, strong, heat-resistant materials used for both mechanical and dielectric applications. Silicone-glass laminates have low moisture absorption and low dielectric losses, and retain most of their physical and electrical properties for long periods at 260°C .

Laminates may be separated into three groups according to the method of manufacture: high-pressure, low-pressure, and wet lay-up.

High Pressure

Silicone-glass laminates (industrial thermosetting laminates) have excellent dielectric strength and arc resistance, and are normally used as dielectric materials. To prepare high-pressure laminates, glass cloth is first impregnated by passing it through a solvent solution of silicone resin. The resin is dried of solvent and precured by passing the fabric through a curing tower. Laminates are prepared by laying up the proper number of plies of preimpregnated glass cloth and pressing them together at about 6.8 MPa and 177°C for about 1 h. They are then oven-cured at increasing temperatures, with the final cure at about 249°C . The resulting laminates can be drilled, sawed, punched, or ground into insulating components of almost any desired shape. Typical applications include transformer spacer bars and barrier sheets, slot sticks, panel boards, and coil bobbins.

Low Pressure

Silicone-glass laminates made by low-pressure reinforced plastics molding methods usually provide optimum flexural strength, for example, about 272 MPa even after heat aging. They are used for mechanical applications such as radomes, aircraft duct work, thermal barriers, covers for high-frequency equipment, and high-temperature missile parts. In making low-pressure laminates, glass cloth is first impregnated and laid up as described earlier. Since the required laminating pressure can be as low as 0.068 MPa, matched-metal-molding and bag-molding techniques can be used in laminating, making possible greater variety in laminated shapes. Laminates should be after-cured as already described.

Wet Lay-Up

Silicone-glass laminates can now be produced by wet lay-up techniques because of the solventless silicone resins recently developed. Such laminates can be cured without any pressure except that needed to hold the laminate together. This technique should prove especially useful in making prototype laminates, and in short production runs where expensive dies are not justified. Laminates are prepared by wrapping glass cloth around a form and spreading on catalyzed resin, repeating this process until the desired thickness is obtained. The laminate surface is then wrapped with a transparent film, and air bubbles are worked out. Laminates are cured at 149°C and, after the transparent film is removed, postcured at 204°C .

S

Molding Compounds

Silicone molding compounds consist of silicone resin, inorganic filler, and catalyst, which, when molded under heat and pressure, form thermosetting plastic parts. Molded parts retain exceptional physical and electrical properties at high temperatures, resist water and chemicals, and do not support combustion. Specification MIL-M-14E recognizes two distinctly different types of silicone molding compounds: type MSI-30 (glass-fiber filled) and type MSG (mineral filled). Requirements for both are as follows.

Type MSI-30

Glass-filled molded parts have high strengths, which become greater the longer the fiber length of the glass filler. Where simple parts can be compression-molded from a continuous fiber length compound, strengths will be approximately twice as great. Properly cured glass-fiber-filled molded parts can be exposed continuously to temperatures as high as 371°C and intermittently as high as 538°C. The heat-distortion temperature after postcure is 482°C. Because of the flow characteristics of these fiber-filled compounds, their use is generally limited to compression molding.

Type MSG

Mineral-filled compounds are free-flowing granular materials. They are suitable for transfer molding and can be used in automatic preforming at molding machines. They are used to make complex parts that retain their physical and electrical properties at temperatures above 260°C but that do not require impact strength. Silicon molding compounds are excellent materials for making Class H electrical insulating components such as coil forms, slot wedges, and connector plugs. They have many potential applications in the aircraft, missile, and electronic industries.

Foaming Powders

Silicone foaming powders are completely formulated, ready-to-use materials that produce heat-stable, nonflammable, low density silicone foam structures when heated. Densities vary from 162 to 288 kg/m³, and compressive strength from 0.68 to 2.23 MPa. Electrical properties are excellent, and water absorption after 24 h immersion is only 2.5%. The maximum continuous operating temperature of these forms is about 343°C.

Foams are prepared by heating the powders to between 149°C and 177°C for about 2 h. The powder can be foamed in place, or foamed into blocks and shaped into woodworking tools. Foams are normally after-cured to develop strength, but can often be cured in service.

Silicone foams are being used in the aircraft and missile industries to provide lightweight thermal insulation and to protect delicate electronic equipment from thermal shock. They can also be bonded to silicone-glass laminates or metals to form heat- and moisture-resistant sandwich structures.

Potting Resins

Solventless silicone resins can be used for impregnating, encapsulating, and potting of electrical and electronic units. Properly catalyzed, filled, and cured, they form tough materials with good physical and electrical properties, and will withstand continuous temperatures of 204°C and intermittent temperatures above 260°C.

Typical physical properties of cured resins include flexural strength of 48.6 MPa, compressive strength of 117 MPa, and water absorption of 0.04%.

Before use, resins are catalyzed with dicumyl peroxide or di-tertiary butyl peroxide. Resins can be simply poured in place, although vacuum impregnation is suggested where fine voids must be filled. Fillers such as glass beads or silica flour are added to extend the resin; their use increases physical strength and thermal conductivity but decreases electrical properties. The resin is polymerized by heating it to about 149°C, and postcured, first at 204°C, then at the intended operating temperature if higher.

Electrical Varnishes

Silicone varnishes (solvent solutions of silicone resins) has made possible the new high-temperature classes of insulation for electrical motors and generators. Silicone insulating varnishes will withstand continuous operating temperatures at 177°C or higher.

Electrical equipment that operates at higher temperatures makes possible motors, generators, and transformers that are much smaller and lighter, or equipment that delivers 25%–50% more power from the same size and still has a much longer service life.

The resinous silicone materials used in Class H electrical insulating systems include the following:

1. Silicone bonding varnish for glass-fiber-covered magnet wire
2. Silicone varnishes for impregnating and bonding glass cloth, mica, asbestos paper. Sheet installations made of these heat-resistant materials are used as slot liners for electric motors and as phase insulation.
3. Silicone dipping varnish that impregnates, bonds, and seals all insulating components into an integrated system.

Other silicone materials used in electrical equipment include silicone rubber lead wire, silicone-adhesive-backed glass tape, and temperature-resistant silicone bearing greases. Silicone insulated motors, generators, and transformers are now being produced by the leading electrical equipment manufacturers.

Uses

The wide range of structural variations of silicone resins makes it possible to tailor compositions for many kinds of applications. Low-molecular-weight silanes containing amino or other functional groups are used as treating or coupling agents for glass fiber and other reinforcements to cause unsaturated polyesters and other resins to adhere better.

The liquids, generally dimethyl silicones of relatively low molecular weight, have a low surface tension, great wetting power and lubricity for metals, and very small change in viscosity with temperature. They are used as hydraulic fluids; as antifoaming agents; as treating and waterproofing agents for leather, textiles, and masonry; and in cosmetic preparations. The greases are particularly desired for applications requiring effective lubrication at very high and at very low temperatures.

Silicone resins are used for coating applications in which thermal stability in the range 300°C–500°C is required. The dielectric properties of the polymers make them suitable for many electrical applications, particularly in electrical insulation that is exposed to high temperatures and as encapsulating materials for electronic devices.

Silicone enamels and paints are more resistant to chemicals than most organic plastics, and when pigmented with mineral pigments

will withstand temperatures up to 538°C. For lubricants, the liquid silicones are compounded with graphite or metallic soaps and will operate between -46°C and 260°C. The silicone liquids are stable at their boiling points, between 399°C and 427°C, and have low vapor pressures, so that they are also used for hydraulic fluids and heat-transfer media. Silicone oils, used for lubrication and as insulating and hydraulic fluids, are methyl silicone polymers. They retain a stable viscosity at both high and low temperatures. As hydraulic fluids, they permit smaller systems to operate at higher temperatures. In general, silicone oils are poor lubricants compared with petroleum oils, but they are used for high temperatures, 150°C–200°C, at low speeds and low loads.

Silicone resins are blended with alkyd resins for use in outside paints, usually modified with a drying oil. Silicone-alkyd resins are also used for baked finishes, combining the adhesiveness and flexibility of the alkyd with the heat resistance of the silicone. A phenyl ethyl silicone is used for impregnating glass-fiber cloth for electrical insulation and it has about double the insulating value of ordinary varnished cloth.

Silicone Rubber

Silicone rubbers are a group of synthetic elastomers noted for their (1) resilience over a very wide temperature range, (2) outstanding resistance to ozone and weathering, and (3) excellent electrical properties.

Composition

The basic silicone elastomer is a dimethyl polysiloxane. It consists of long chains of alternating silicon and oxygen atoms, with two methyl side chains attached to each silicon atom. By replacing a part of these methyl groups with other side chains, polymers with various desirable properties can be obtained. For example, where flexibility at temperatures lower than -57°C is desired, a polymer with about 10% of the methyl side chains replaced by phenyl groups will provide compounds with brittle points below -101°C. Side chain modification can also be used to produce elastomers with lower compression set, to increase resistance to fuels, oils, or solvents, or to permit vulcanization at room temperature.

Curing, or vulcanization, is the process of introducing cross-links at intervals between the long chains of the polymer. Silicone rubbers are usually cross-linked by free radical-generating curing agents, such as benzoylperoxide, which are activated by heat, or the cross-linking can be accomplished by high-energy radiation beams. Room temperature vulcanized compounds are cross-linked by the condensation reaction resulting from the action of metal-organic salts, such as zinc and tin octoates. Pure polymers upon cross-linking change from viscous liquids into elastic gels with very low tensile strength. To attain satisfactory tensile strength, reinforcing agents are necessary. Synthetic and natural silicas and metallic oxides are commonly used for this purpose. In addition to the vulcanizing agents and reinforcing fillers described, other additives may be incorporated into silicone compounds to pigment the stock, to improve processing, or to reduce the compression set of certain types of silicone gum.

Ordinary silicone rubber has the molecular group $\text{H} \cdot \text{CH}_2 \cdot \text{Si} \cdot \text{CH}_2 \cdot \text{H}$ in a repeating chain connected with oxygen linkages, but in the nitrile-silicone rubber one of the end of hydrogens of every fourth group in the repeating chain is replaced by a C:N radical. These polar nitrile groups give a little affinity for oils, and the rubber does not swell with oils and solvents. They retain strength and flexibility at temperatures from -73°C to above 260°C, and is used for such

products as gaskets and chemical hose. As lubricants, silicones retain a nearly constant viscosity at varying temperatures. Fluorosilicones have fluoroalkyl groups substituted for some of the methyl groups attached to the siloxane polymer of dimethyl silicone. They are fluids, greases, and rubbers, incompatible with petroleum oils and insoluble in most solvents. The greases are the fluids thickened with lithium soap or with a mineral filler.

Types

Silicone-rubber compounds can be conveniently grouped into several major types according to characteristic properties. According to one such classification system, the types are (1) general purpose, (2) extremely low temperature, (3) extremely high temperature, (4) low compression set, (5) high strength, (6) fluid resistant, (7) electrical, and (8) room temperature vulcanizing rubbers.

1. General-purpose compounds are available in Shore A hardnesses from 30 to 90, tensile strengths of 4.8–8.24 MPa, and ultimate elongations of 100%–500%. The service temperature range extends from -55°C to 260°C, and they have good resistance to heat and oils, along with good electrical properties. Many of these compounds contain semireinforcing or extending fillers to lower their cost.
2. Extremely low temperature compounds have brittle points near -118°C and are quite flexible at -84°C to -90°C. Their physical properties are usually about the same as those of the general-purpose stocks, with some reduction in oil resistance.
3. Extremely high temperature compounds are considered serviceable for over 70 h at 343°C and will withstand brief exposures at higher temperatures; for example, 4–5 h at 371°C and 10–15 min at 399°C. In comparison, general-purpose compounds are limited to about 260°C for continuous service in 316°C for intermittent service.
4. Low-compression-set compounds provide typical values of 10%–20% compression set after 22 h at 149°C. They have improved resistance to petroleum oils and various hydraulic fluids, and are particularly suitable for use in O-rings and gaskets.
5. High-strength compounds, in Shore A hardnesses of 25–70, provide tensile strengths from 0.82 to over 136 MPa and elongations from 400% to 700%, with tear strengths from 26,790 to 58,045 g/cm. Compounds of this class may operate over a service temperature range from -90°C to 316°C.
6. Excellent resistance to a wide range of fuels, lubricants, and hydraulic fluids is offered by compounds based on a silicone polymer with 50% of its side methyl groups substituted by trifluoropropyl groups. Physical properties are similar to properties of other types of silicone compounds. However, service temperature range is somewhat limited. Its low-temperature properties are about the same as those of the dimethyl polymer, with the brittle point around -68°C and an upper service temperature of around 260°C.
7. In general, silicone-rubber compounds have excellent electrical properties, which, along with their resistance to high temperatures, make them suitable for many electrical applications. With proper compounding, dielectric constant can be easily vary from about 2.7 to 5.0 or higher, while the power factor can be varied from 0.0005 up to 0.1 or higher. The volume resistivity of a typical silicone

S

compound will be in the range of 10^{14} to $10^{16} \Omega \text{ cm}$ and its dielectric strength will be about 450–550 V/mil thickness (measured on a slab 2.0 mm). Resistance to corona is excellent and water absorption is low. In most cases, excellent electrical properties are retained over a wide temperature and frequency range. Compounds can also be prepared with very low resistivity, as low as about $10 \Omega \text{ cm}$, for special applications. Insulated tapes for cable-wrapping applications can be prepared from electrical-grade compounds with a partial cure or from a completely cured self-adhering silicone compound.

8. Room-temperature vulcanizing silicone rubbers are available to provide most of the performance characteristics of silicone rubbers in compounds that cure at room temperature.

In addition to having excellent heat resistance, silicone rubbers retain their properties to a much greater extent at high temperatures than do most organic rubbers. For example, a silicone compound with a tensile strength at temperature of 1.36 MPa will have a tensile strength at 316°C of 0.48 MPa or over. Most organic rubbers, although their initial properties are much higher, will be virtually useless at 260°C (except for the fluoroelastomers). In applications where a silicone rubber part operates in low oxygen atmosphere, such as sealing on high-altitude aircraft, its heat resistance will be still further improved.

In using silicone rubber at high temperatures, care must be taken to prevent reversion or depolymerization, which may occur where a part is required to operate in an enclosed environment. Here again, where this problem cannot be eliminated by the design engineer, the silicone-rubber fabricator can produce compounds with relatively high resistance to reversion.

Fabrication and Uses

In general, silicone rubbers may be handled on standard rubber-processing equipment. Their fabrication differs from that of organic rubbers chiefly in that uncured silicone compounds are softer and tackier and have much lower green strength. Also, an oven post-cure in a circulating air oven is often required after vulcanization to obtain optimum properties. Silicone rubbers can be extruded, molded, calendered, sponged, and foamed. Since compounding of the rubber stock determines to a great extent the processing characteristics of the material, the fabricator should be consulted before the material is specified, to determine whether compromises are necessary to obtain the best combination of physical properties and the most desirable shape. Silicone-rubber compounds can also be applied to fabrics by calender coating, knife spreading, or solvent dispersion techniques.

For certain applications, very soft or low durometer materials are required. Suitable for such applications are low durometer solid silicone rubbers, closed or open cell expanded silicone rubbers (designated here as sponge and foam, respectively), and fibrous silicone rubber.

Silicone-rubber sponge is available in molded sheets, extrusions, and simple molded shapes. As in the case of solid silicone rubber, improved resistance to fluids or abrasion can be obtained by bonding molded or extruded sponge to a fabric or plastic cover. Silicone foam rubber can be fabricated in heavy cross-sections and complex shapes, and can be foamed and vulcanized either at ambient or elevated temperature. It is suitable for use where an extremely soft, low-density silicone material is required. Like sponged, it can be bonded to fabrics on plastics.

For some applications a solid, low durometer material has advantages over sponge or foam. For example, it should probably be specified for gaskets or seals where the low compression set of foam, the compression–deflection characteristics of sponge, and the higher tensile and tear strength of solid silicone rubbers must be combined.

The last highly compressible material, fibrous silicone rubber, consists of hollow rubber fibers sprayed in a random manner and bonded into a low-density porous mat. Its properties include excellent compression set combined with good tear and tensile strength, and very high porosity. As manufactured at present, it is serviceable from –55°C to over 260°C, and is available in mats 3.2 mm thick and 228 mm wide.

Silicone rubbers are most widely used in the aircraft, electrical, and automotive industries, although their unique properties have created many other applications. Specific examples would include seals for aircraft canopies or access doors, insulation for wire and cable, dielectric encapsulation of electronic equipment, and gaskets or O-rings for use in aircraft automobile engines. An example of another field in which they are useful is the manufacture of stoppers for pharmaceutical vials, since silicone rubbers are tasteless, odorless, and nontoxic.

Siliconizing

- (1) Diffusing silicon into solid metal, usually low carbon steels, at an elevated temperature in order to improve corrosion or wear resistance.
- (2) A process for developing a silicon rich layer on steel by packing a component in ferrosilicon and heating at about 900°C for a few hours. The layer has good wear and oxidation resistance.

Silk

Silk is the fibrous material in which the silkworm, or larva of the moth, envelops itself before passing into the chrysalis state. Silk is closely allied to cellulose and resembles wool in structure, but unlike wool it contains no sulfur. The natural silk is covered with a wax or silk glue, which is removed by scouring in manufacture, leaving the glossy fibroin, or raw-silk fiber. The fibroin consists largely of the amino acid alanine, which can be synthesized from pyruvic acid. Silk fabrics are used mostly for fine garments but are also valued for military powder bags because they burn without a sooty residue.

The fiber is unwound from the cocoon and spun into threads. The chief silk producing countries are China, Japan, India, Italy, and France. Floss silk is a soft silk yarn practically without twist, or is the loose waste silk produced by the worm when beginning to spin its cocoon.

Satin is a heavy silk fabric with a close twill weave in which the fine warp threads appear on the surface and the weft threads are covered by the peculiar twill. Common satin is of eight-leaf twill, the weft intersecting and binding down the warp at every eighth pick, but 16–20 twirls are also made. In the best satins, a fine quality of silk is used.

Silky Fracture

A metal fracture in which the broken metal surface has a fine texture, usually dull in appearance. Characteristic of tough and strong metals. Contrast with *crystalline fracture* and *granular fracture*.

Silver and Alloys

A white metal (symbol Ag), silver is very malleable and ductile, and is classed with the precious metals. It occurs in the native state, and

also combined with sulfur and chlorine. Copper, lead, and zinc ores frequently contain silver; about 70% of the production of silver is a by-product of the refining of these metals.

Silver is the whitest of all the metals and takes a high polish, but easily tarnishes in the air because of the formation of a silver sulfide. It has the highest electrical and heat conductivity: 108% IACS relative to 100% for the copper standard and about 422 W/(m K), respectively. Cold work reduces conductivity slightly. The specific gravity is 10.7, and a melting point is 962°C. When heated above the boiling point (2163°C), it passes off as a green vapor. It is soluble in nitric acid and in hot sulfuric acid. The tensile strength of cast silver is 282 MPa, with Brinell hardness 59. The metal is marketed on a troy-ounce value.

Pure silver has the highest thermal and electrical conductivity of any metal, as well as the highest optical reflectivity. It is the most ductile and most malleable of any metal next to gold. Silver can be hammered into sheet 0.01 mm thick or drawn out in wire so fine 120 m would weigh only 1 g. Classified as one of the most corrosion-resistant metals, silver, under ordinary conditions, will not be affected by caustics or corrosive elements, unless hydrogen sulfide is present, causing silver sulfide to form. Silver will dissolve rapidly in nitric acid and more slowly in hot concentrated sulfuric acid. Unless oxidizing agents are present, the action of diluted or cold solutions of sulfuric acid is negligible. Organic acids generally do not attack the metal and caustic alkalies have but a slight effect on pure silver.

Although silver tarnishes quickly in the presence of sulfur and sulfur-bearing compounds, it oxidizes slowly in air and the oxide decomposes at a relatively low temperature.

Classification

Silver is classified by grades in parts per thousand based on the silver content (impurities are reported in parts per hundred). Commercial grades are fine silver and high fine silver. As ordinarily supplied, fine silver contains at least 999.0 parts silver per thousand, and they go as high as 999.3 parts per thousand. Any of the common base metals may be present, although copper is usually the major impurity. Any silver of higher purity than commercial fine contains its purity in its description, that is, 999.7 high fine silver. The purest silver obtainable in quantity is 999.9 plus; the impurities are less than 0.01 part per thousand. Fine silver may also contain small percentages of oxygen or hydrogen; deoxidized silver is available for applications where these elements may be a detriment.

Fabricability

Silver can be cold-worked, extruded, rolled, swaged, and drawn. It can be cold-rolled or cold-drawn drastically between anneals, and can be annealed at relatively low temperatures. To prevent oxidation when casting by conventional methods, silver should be protected by a layer of charcoal or by melting under neutral or reducing gas. Deoxidation by adding lithium or phosphorus can be obtained leaving a residual content of 0.01% max. The excellent ductility of silver makes it readily workable hot or cold.

Molten silver will absorb approximately 20 times its own volume of oxygen. Most of this oxygen is given up when the silver solidifies in cooling, but care should be taken in melting and casting because any oxygen left in the cast bars will cause cracking when they are fabricated and the castings may have blowholes.

Galling, seizing of the tool, and surface tearing are problems encountered when sheeting fine silver. This can be somewhat alleviated by using material cold-worked as much as possible.

Joining

Fine silver can be soldered without difficulty using tin-lead solders. Boron-silver filler metal can be used in brazing, and welding can be done by resistance methods and by atomic hydrogen or inert-gas shielded arc processes. A range of 204°C–427°C is recommended for annealing, with best strength and ductility achieved between 371°C and 427°C. Little additional softening occurs at higher temperatures, which may induce welding of adjacent surfaces. The lighter the gauge, the lower should be the annealing temperature.

Applications of Alloys and Compounds

Because silver is a very soft metal, it is not normally used industrially in a pure state, but is alloyed with a hardener usually copper. Sterling silver is a name given to a standard high-grade alloy containing a minimum of 925 parts in 1000 of silver. It is used for the best tableware, jewelry, and electrical contacts. This alloy of 7.5% copper work hardens and requires annealing between roll passes. Silver can also be hardened by alloying with other elements.

The standard types of commercial silver are fine silver, sterling silver, and coin silver. Fine silver is at least 99.9% pure and is used for plating, making chemicals, and for parts produced by powder metallurgy. Coin silver is usually an alloy of 90% silver and 10% copper, but when actually used for coins, the composition and weight of the coin are designated by law. Silver and gold are the only two metals that fulfill all the requirements for coinage. The so-called coins made from other metals are really official tokens, corresponding to paper money, and are not true coins. Coin silver has a Vickers hardness of 148 compared with a hardness of 76 for hard-rolled pure silver. It is also used for silverware, ornaments, plating, for alloying with gold, and for electric contacts. Silver is not an industrial metal in the ordinary sense. It derives its coinage value from its intrinsic aesthetic value for jewelry and plate, and in all civilized countries silver is a controlled metal.

Silver powder, 99.9% purity, for use in coatings, integrated circuits, and other electrical and electronic applications, is produced in several forms. Amorphous powder is made by chemical reduction and comes in particle sizes of 0.9–1.5 μm . Powder made electrolytically is in dendritic crystals with particle sizes from 10 to 200 μm . Atomized powder has spherical particles and may be as fine as 400 mesh. Silver-clad powder for electric contacts is a copper powder coated with silver to economize on silver. Silver flaky is in the form of laminar platelets and is particularly useful for conductive and reflective coatings and circuitry. The tiny flat plates are deposited in overlapping layers permitting a metal weight saving of as much as 30% without reduction of electrical properties.

Nickel-coated silver powder, for contacts and other parts made by powder metallurgy, comes in grades with 1/4%, 1/2%, 1%, and 2% nickel by weight.

The porous silver comes in sheets in standard porosity grades from 2 to 55 μm . It is used for chemical filtering.

Silver plating is sometimes done with a silver-tin alloy containing 20–40 parts silver and the remainder tin. It gives a plate having the appearance of silver but with better wear resistance. Silver plates have good reflectivity at high wavelengths, but reflectivity falls off at about 350 nm, and is zero at 3000, so that it is not used for heat reflectors.

Silver-clad sheet, made of a cheaper nonferrous sheet with a coating of silver rolled on, is used for food-processing equipment. It is resistant to organic acids but not to products containing sulfur. Silver-clad steel, used for machinery bearings, shims, and reflectors, is made with pure silver bonded to the billet of steel and then rolled.

S

For bearings, the silver is 0.025–0.889 cm thick, but for reflectors of silver is only 0.003–0.008 cm thick. Silver-clad stainless steel is stainless-steel sheet with a thin layer of silver rolled on one side for electrical conductivity.

Silver iodide is a pale-yellow powder of the composition AgI, best known for its use as a nucleating agent and for seeding rain clouds. Silver nitrate, formally known as lunar caustic, is a colorless, crystalline, poisonous, and corrosive material of the composition AgNO₃. It is used for silvering ring mirrors, for silver plating, in indelible inks, and medicine, and for making other silver chemicals. The high-purity material is made by dissolving silver and nitric acid, evaporating the solution, and crystallizing the nitrate, then redissolving the crystals in distilled water and recrystallizing. It is an active oxidizing agent. Silver chloride, AgCl, is a white granular powder used in silver-plating solutions. This salt of silver and other halogen compounds of silver, especially silver bromide, AgBr, are used for photographic plates and films. Silver chloride is used in the preparation of yellow glazes, purple of Cassius, and silver lusters. A yellowish silver luster is obtained by mixing silver chloride with three times its weight of clay and ochre and sufficient water to form a paste.

Silver chloride crystals in sizes up to 4.5 kg are grown synthetically. The crystals are cubic, and can be heated and pressed into sheets. The specific gravity is 5.56, index of refraction is 2.071, and melting point is 455°C. They are slightly soluble in water and soluble in alkalis. The crystals transmit more than 80% of the wavelengths from 50 to 200 μ m.

Silver sulfide, Ag₂S, is a gray-black, heavy powder used for inlaying in metal work. It changes its crystal structure at about 179°C, with a drop in electrical resistivity, and is also used for self-resetting circuit breakers. Silver potassium cyanide, KAg(CN)₂, is a white, crystalline, poisonous solid used for silver-plating solutions. Silver tungstate, Ag₂WO₄, silver manganate, AgMnO₄, and other silver compounds are produced in purity grades for electronic and chemical uses.

Silver nitrate, AgNO₃, with a melting point of 212°C, and decomposes at 444°C and is soluble, corrosive, and poisonous. It is prepared by the action of nitric acid on metallic silver. Silver nitrate is the most convenient method of introducing silver into a glass; a solution of the compound is poured over the batch.

The photosensitive halides are used in photography, the cyanides are used in electroplating, and most of the minor silver salts are prepared from silver nitrate.

In advanced ceramic applications, silver is unsurpassed as a conductor of heat and electricity. Silver is used in conductive coatings for capacitors, printed wiring, and printed circuits on titanites, glass-bonded mica, steatite, alumina, porcelain, glass, and other ceramic bodies. These coatings are also used to metallize ceramic parts to serve as hermetically sealed enclosures, becoming integral sections of coils, transformers, semiconductors, and monolithic and integrated circuits.

Two types of conductive coatings can be used on ceramic parts; those that are fired on and those that are baked on or air dried. The fired-on type contains, in addition to silver powder, a finely divided low-melting glass powder, temporary organic binder, and liquid solvents in formulations with direct soldering properties and other suitable for electroplating, both possessing excellent adhesion and electrical conductivity. The baked-on and air-dry types contain, in addition to silver powder, a permanent organic binder and liquid solvents. These preparations have somewhat less adhesion, electrical conductivity, and solderability than the fired-on type, but can be electroplated if desired. The air-dry type is used when it is not desirable to subject the base material to elevated firing temperatures.

Any of the aforementioned silver compositions are available in a variety of vehicles suitable for application by squeegee, brushing, dipping, spraying, bonding wheel, roller coating, etc.

Firing temperatures for direct-solder silver preparations range from 677°C to 788°C. Silver compositions to be copper plated are fired at 1200°F–1250°F. The firing cycle used with these temperatures will vary from 10 min to 6 h, depending on the time required to equalize the temperature of the furnace charge.

A 62% Sn–36% Pb–2% Ag solder is generally used with the direct-solder silver compositions. It is recommended that this solder be used at a temperature of 213°C–219°C. Soldering to the plated silver coating is less critical and 50% Sn–50% Pb, as well as other soft solders, are being used with good results.

The air-dried silver compositions will, as the designation implies, air dry at room temperature in approximately 16 h. This drying time can be shortened by subjecting the coating to temperatures of 60°C–93°C for 10–30 min. The baked-on preparations must be cured at a minimum temperature of 149°C for 5–16 h. The time may be shortened to 1 h by raising the temperature to 301°C.

The same soft solders and techniques as recommended for the fired-on coatings may be used for the electroplated air-dried and baked-on preparations. It is extremely difficult to solder to air-dried or baked-on coatings without first electroplating.

The surface conductivity of the fired silver coating is far better than that of the air-dried or baked-on coating. Fired coatings have a surface electrical square resistance of approximately 0.01 Ω while the surface electrical square resistance of air-dried or baked-on is about 1 Ω .

Usually Alloyed

Because pure silver is so soft, it is usually alloyed with other metals for strength and durability. The most common alloying metal is copper, which imparts hardness and strength without appreciably changing the desirable characteristics of silver. Sterling silver has applications in manufacturing processes. For example, sterling silver plus lithium has been used in the aircraft industry for bracing honeycomb sections. Other silver–copper alloys are coin silver, 90.0% silver, 10.0% copper, and the silver–copper eutectic, 72% silver, 28% copper. This latter alloy has the highest combination of strength, hardness, and electrical properties of any of the silver alloys.

Silver braze filler metals are widely used for joining virtually all ferrous and nonferrous metals, with the exception of aluminum, magnesium, and some other lower-melting point metals. Whereas pure silver melts at 960°C, silver alloys, with compositions of 10%–85% silver (the alloying metals are copper, zinc, cadmium, and/or other base metals), have melting points of 618°C–960°C. These alloys have the ductility and malleability and can be rolled into sheet or drawn into wire of very small diameter. They may be employed in all brazing processes and are generally free-flowing when molten. Recommended joint clearances are 0.05–0.13 mm when used with flux. Whereas fluxes are usually required, zinc and cadmium-free alloys can be brazed in a vacuum or in reducing or inert atmospheres without flux. Joints made with silver brazing filler metals are strong, ductile, and highly resistant to shock and vibration. With proper design, there is no difficulty in obtaining joint strength equal to or greater than that of the metals joined. The strongest joints have but a few thousandths of an inch of the alloy as bonding material. Typical joints made with silver brazing filler metals, giving the greatest degree of safety, are scarf, lap, and butt joints.

For electrical contacts, silver is combined with a number of other metals, which increased hardness and reduce the tendency to sulfide tarnishing. Silver–cadmium, for example, is extensively used for

contacts, with the cadmium ranging from 10% to 15%. The advantages of these alloys are resistance to sticking or welding, more uniform wear, and a decreased tendency for metal transfer.

Alloys used for contact and spring purposes are the silver-magnesium-nickel series (99.5% silver), which are used where electrical contacts are to be joined by brazing without loss of hardness, in miniature electron tubes for spring clips where high thermal conductivity is essential, and for instruments and relay springs requiring good electrical conductivity at high temperatures. These are unique, oxidation-hardening alloys. Before being hardened, the silver-magnesium-nickel alloy can be worked by standard procedures. After hardening in an oxidizing atmosphere, the room-temperature tensile properties are similar to those of hard rolled sterling silver or coin silver.

Gold and palladium are also combined with silver for contact use because they reduce welding and tarnishing and, to some extent, increase hardness.

When certain base metals do not combine with silver by conventional methods, powder metal processes are employed. This is particularly true of silver-iron, silver-nickel, silver-graphite, silver-tungsten, etc. these alloys are used in electrical contacts because of the desirable conductivity of silver and the mechanical properties of the base metals. They can be pressed, centered, and rolled into sheet and wire that as ductile unsuitable for forming into contacts by heading or stamping operations.

Other silver products are those produced chemically—powder, flake, oxide, nitrate, and paint. Silver powder and flake are composed of large amounts of silver with 0.03% or 0.04% copper and traces of lead, iron, and other volatiles.

Silvering

The application of a reflecting surface to glass. Techniques including chemical deposition and various solutions and sputtering or vapor deposition.

Silver Paints

These are used as conductive coatings that are pigmented with metallic silver flake or powder and bonding agents that are specially selected for the type of base material to which they are applied. These coatings are used to make conductive surfaces on such materials as ceramics, glass, quartz, mica, plastics, and paper, as well as on some metals. They are used for making printed circuits, resistor and capacitor terminals, and in miniature electrical instruments and equipment. Silver paints fall into two classifications: (1) fired-on types for base materials, they can withstand temperatures in the 399°C–927°C range, and (2) air-dried or baked-on types for organic base materials that are dried at temperatures ranging from 21.1°C to 427°C. The bonding agent in the fired-on type of coating is a powdered glass frit, whereas in the air-dried or baked-on type of coating organic resins are used. The viscosity and drying rate of each type varies, depending on the methods of application, such as spraying, dipping, brushing, roller coating, or screen stenciling.

Silver Solder

Brazing alloys, also termed hard solders are based mainly on silver, copper, zinc and cadmium, for example, 50% silver, 19% cadmium, 16% zinc and 15% copper. The various filler metals have melting ranges commencing at about 620°C (the eutectic for the alloy), i.e., intermediate between the tin lead solders and the high copper brass fillers.

Their strength is similar to the braze fillers i.e., better than the solders. Silver solders are not confined to joining silver components but have applications for steel and copper items where the requirements of strength and relatively low melting point justify the cost.

High-melting-point solder employed for soldering joints where more than ordinary strength and, sometimes, electrical conductivity are required. Most silver solders are copper-zinc brazing filler metals with the addition of silver. They may contain 9% to 80% silver, and the color varies from brass yellow to silver white. Cadmium may also be added to lower the melting point. Some solders do not necessarily contain zinc, and alloys of silver and copper in proportions are arranged to obtain the desired melting point and strength. A silver solder with their relatively low melting point contain 65% silver, 20% copper, and 15% zinc. It melts at 693°C, has a tensile strength of 447 MPa, and elongation 34%. The electrical conductivity is 21% that of pure copper. A solder melting at 760°C contains 20% silver, 45% copper, and 35% zinc. **ASTM silver solder No. 3** is this solder with 5% cadmium replacing an equal amount of the zinc. It is a general-purpose solder. **ASTM silver solder No. 5** contains 50% silver, 34% copper, and 16% zinc. It melts at 693°C and is used for soldering electrical work and refrigeration equipment.

Any tin present in silver solders makes them brittle; lead and iron make the solders difficult to work. Silver solders are malleable and ductile and have high strengths. They are also corrosion-resistant and are especially valuable for use in food machinery and apparatus where lead is objectionable. Small additions of lithium to silver solders increase fluidity and wetting properties, especially for brazing stainless steels or titanium. **Sil-Fos**, is a phosphor-silver brazing solder with a melting point of 704°C. It contains 15% silver, 80% copper, and 5% phosphorus. Lap joints brazed with Sil-Fos have a tensile strength of 207 MPa. The phosphorus in the alloy acts as a deoxidizer, and the solder requires little or no flux. It is used for brazing brass, bronze, and nickel alloys. The grade goes by the name of Easy solder contains 65% silver, melts at 718°C, and is a color match for sterling silver. **TL silver solder** has only 9% silver in melts at 871°C. It is brass yellow in color and is used for brazing nonferrous metals. **Sterling silver solder**, for brazing sterling silver, contains 92.8% silver, 7% copper, and 0.2% lithium. Flow temperature is 899°C.

A lead-silver solder recommended to replace tin solder contains 96% lead, 3% silver, and 1% indium. It melts at 310°C, spreads better than ordinary lead-silver solders, and gives a joint strength of 34 MPa. **Silver-palladium alloys** for high-temperature brazing contain 5% to 30% palladium. With 30%, the melting point is about 1232°C. These alloys have exceptional melting and flow qualities and are used in electronic and spacecraft applications.

Silver Soldering

Nonpreferred term used to denote brazing with a silver-based filler metal. See preferred terms *furnace brazing*, and *induction brazing*, and *torch brazing*.

Silver Steel

A high carbon steel supplied as softened bright precision ground bar or strip for machining purposes. It does not contain silver. See *steel*.

Silver-Type Batteries

Because they are six times lighter and five times smaller than other batteries of similar capacity, silver-zinc batteries have found wide

S

use in guided missiles, Tele metering equipment, and guidance control circuits and mechanisms. Where longer life and ruggedness are more important than the weight, silver–cadmium rechargeable batteries are specified. Where seawater activation is required, silver chloride–magnesium couples are used. Another silver type of battery is the solid electrolyte type made with silver, silver iodide, and vanadium pentoxide. This battery, designed for low-current applications, weighs less than 1 oz and has almost unlimited shelf life.

Single-Action Press

A metal forming press that provides pressure from one side.

Single-Bevel Groove Weld

A groove weld in which the joint edge of one member is beveled from one side.

Single-Circuit Winding

In forming of plastics and composites, a winding in which the filament path makes a complete traverse of the chamber, after which the following traverse lies immediately adjacent to the previous one. See also *filament winding*.

Single Crystals

In crystalline solids the atoms or molecules are stacked in a regular manner, forming a three-dimensional pattern, which may be obtained by a three-dimensional repetition of a certain pattern unit called a unit cell. When the periodicity of the pattern extends throughout a certain piece of material, one speaks of a single crystal. A single crystal is formed by the growth of a crystal nucleus without secondary nucleation or impingement on other crystals.

Growth Techniques

Among the most common methods of growing single crystals are those of P. Bridgman and J. Czochralski. In the Bridgman method the material is melted in a vertical cylindrical vessel that tapers conically to a point at the bottom. The vessel then is lowered slowly into a cold zone. Crystallization begins in the tip and continues usually by growth from the first forward nucleus. In the Czochralski method, a small single crystal (seed) is introduced into the surface of the melt and then drawn slowly upward into a cold zone. Single crystals of ultrahigh purity have been grown by zone melting. Single crystals are also often grown by bathing a seed with a supersaturated solution; the super saturation is kept lower than is necessary for sensible nucleation.

When grown from a melt, single crystals usually take the form of their container. Crystals grown from solution (gas, liquid, or solid) often have a well-defined form that reflects the symmetry of the unit cell.

Physical Properties

Ideally, single crystals are free from internal boundaries. They give rise to a characteristic x-ray diffraction pattern. For example, the Laue pattern of a single crystal consists of a single characteristic set of sharp intensity maxima.

Many types of single crystals exhibit anisotropy, that is, a variation of some of their physical properties according to the direction

along which they are measured. For example, the electrical resistivity of a randomly oriented aggregate of graphite crystallites is the same in all directions. The resistivity of a graphite single crystal is different, however, when measured along different crystal axes. This anisotropy exists for both structure-sensitive properties, which are not affected by imperfections (such as elastic coefficients).

Anisotropy of a structure-sensitive property is described by a characteristic set of coefficients that can be combined to give the macroscopic property along any particular direction in the crystal. The number of necessary coefficients can often be reduced substantially by consideration of the crystal symmetry; whether anisotropy, with respect to a given property, exists depends on crystal symmetry.

And the structure-sensitive properties of crystals (for example, strength and diffusion coefficients) seemed governed by internal defects, often on an atomic scale.

Industry and government are developing one of the first accurate computer-model predictions of molten metals and molding materials used in casting.

Currently, the computer information is being used to design and cast aircraft turbine blades. Similarly, another company is using the information from the computer models to improve the casting of automobile and light truck engine blocks.

Cast-metal parts are used in 90% of all durable goods such as washing machines, refrigerators, stoves, lawnmowers, cars, boats, and aircraft. The goal of the partnership is to produce accurate models for all alloys used by the casting industry. The information can then be used by manufacturers to standardize metal mixing recipes, allowing more effective competition in the marketplace.

Single-Crystal Superalloys

The nickel-base alloys that contain a single crystal, or more accurately, a single grain or primary dendrite. Because these materials have no grain boundaries, they exhibit improved high-temperature properties and corrosion resistance.

Single-Impulse Welding

Spot, projection, or upset welding by a single impulse of current. Where alternating current is used, an impulse may be any fraction or number of cycles.

Single-J Groove Weld

A groove weld in which the joint edge of one member is prepared in the form of a J, from one side. See also the term *single-bevel groove weld*.

Single-Lap Shear Specimen

In adhesive testing, a specimen made by bonding the overlapped edges of two sheets or strips of material. In testing, a single-lap specimen is usually loaded in tension at the ends, thereby creating shear stresses at the joint interface.

Single-Point Tool

See nomenclature—*side clearance*, *side relief*, *side rake angle*, *end clearance angle*, *end relief angle*, *end cutting edge angle*, *normal side relief angle*, *normal side clearance angle*, and *nose radius*.

Single-Port Nozzle (Plasma Arc Welding and Cutting)

A constricting nozzle containing one orifice, located below and concentric with the electrode. See the term *multiport nozzle*.

Single Relief Angle

See *single point tool*.

Single Spread

Application of adhesive to only one adherend of a joint.

Single-Stand Mill

A rolling mill designed such that the product contacts only two rolls at a given moment. Contrast with *tandem mill*.

Single-U Groove Weld

A groove weld in which each joint edge is prepared in the form of a J or half-U from one side.

Single-V Groove Weld

A groove weld in which each member is beveled from the same side.

Single Welded Joint

In arc and gas welding, any joint welded from one side only.

Sinkhead

Same as *riser*.

Sinking

(1) The operation of machining the impression of a desired forging into die blocks. (2) See *tube sinking*. (3) In the context of tube manufacture the term refers to drawing without the use of an internal mandrel or plug to control the bore size. See *drawing*. (4) Die sinking.

Sink Mark

A shallow depression on the surface of an injection-molded plastic part due to the collapsing of the surface following local internal shrinkage after the gate seals.

Sinter

To densified, crystallize, bond together, and/or stabilize a particulate material, agglomerate, or product by heating or firing close to but below the melting point. Often involves melting of minor components or constituents, and/or chemical reaction. Also, the product of such firing.

Sinter Hardening

Recognizing the great potential of sinter hardening, researchers continue to develop useful data that will help to attain benefits derived

from this heat treatment. Improved properties can be achieved by effective control of material composition, density, section size, sintering temperature, and cooling rate. By controlling these variables a variety of microstructures and resultant properties are achievable, enabling particular powder metallurgy parts to favorably perform under specific severe conditions. However, material options, process flexibility, and application requirements demand a better understanding of process, microstructure, and mechanical property relationships to capitalize fully on the opportunity of sinter hardening.

Sinter hardening refers to a process where the cooling rate experienced in the cooling zone of the sintering furnace is fast enough that a significant portion of the material matrix transforms to martensite. Interest in sinter hardening has grown because it offers good manufacturing economy by providing a one-step process and a unique combination of strength, toughness, and hardness.

A variety of microstructures and properties can be obtained by varying both the alloy type and content as well as the postsintering cooling rate. By controlling the cooling rate, the microstructure can be manipulated to produce the required proportion of martensite, which will lead to desired mechanical properties. By understanding how the sintering conditions affect the microstructure, materials can be modeled to produce the final properties that are desired.

Alloying

Alloying elements are used in cast, wrought, and P/M materials to promote hardenability and increase the mechanical strength of the parts. A graphical way of examining the effects of alloying elements on the final microstructure of the steel is by using the characteristic isothermal transformation (I-T) diagram. This indicates the time necessary for the isothermal transformation of phases in the material from start to finish, as well as the cooling time and temperature combinations needed to produce the final microstructure. A similar diagram, known as a continuous cooling (CCT) curve, also is frequently used to determine the variation in microstructure as a function of cooling rate.

Materials and Processing

As expected, increasing the cooling rate resulted in increased apparent hardness and strength values. On the whole, hardness values were increased between 2 and 10 HRC for a given material.

As expected, in all materials, the percent of martensite present increased significantly with the increase in cooling rate. The effect of the increased martensite levels is apparent in the hardness values for each of the materials. The effect of the higher levels of martensite on tensile properties is less obvious. In several cases, materials with significantly lower percentages of martensite and lower hardness values demonstrated higher tensile strengths.

Some results show the following trends:

1. Materials with 2 wt% Ni and 0.5 wt% Graphite Admixed
 - a. Accelerated cooling resulted in increase strength and apparent hardness while decreasing elongation values only slightly. This result was a consequence of increased martensite content and finer pearlitic microstructures. In these materials, the martensite was the result of transformation of nickel-rich areas in the microstructure.
 - b. The increase in prealloyed alloy content from 0.85 to 1.5 wt% Mo resulted in a larger increase in strength than the addition of 1.0 wt% admixed Cu.

- c. Although the 0.85 wt% Mo materials exhibited higher percentages of martensite than identical chemistries based on the 1.5 wt% Mo prealloyed material, the higher molybdenum materials had higher apparent hardness and strength values. This surprising result was explained by the presence in the 1.5 wt% Mo-based material of significantly finer pearlite.
2. Materials with 2 wt% Cu and 0.9 wt% Graphite Admixed
 - a. As the cooling rate was increased for these materials, the apparent hardness increased. This was associated with higher martensite contents in the faster-cooled materials. Martensite contents of greater than 50% were found in all three base materials when accelerated cooling was utilized.
 - b. The materials with the highest apparent hardness values (0.5 wt% Ni, 1.5 wt% Mo pre-alloy) did not exhibit the highest tensile strength values. The highest UTS values were determined for the fast-cooled version of the 0.85 wt% Mo prealloyed material. Retained austenite may be one potential cause for the fall off in strength for the Mo–Ni material.

Sintered Density

The quotient of the mass (weight) over the volume of the sintered body expressed in grams per cubic centimeter.

Sintered Density Ratio

The ratio of the density of the sintered body to the solid, pore-free body of the same composition or theoretical density.

Sintering

A process, below the melting point but usually at elevated temperature, in which contacting particles mutually diffuse and bond. The process may be used to agglomerate fine mineral ore dust to make it more easily processed and handled or it may be used to make substantial objects of metal powders for further processing or to directly enter service. If the atmosphere is intended to react with the powder during the operation to promote bonding the process is termed *activated sintering*.

The bonding of adjacent surfaces of particles in a mass of powder or a compact by heating. Sintering strengthens a powder mass and normally produces densification and, in powdered metals, recrystallization. See also *liquid phase sintering* and *solid-state sintering*.

Sintering Atmospheres

See *protective atmosphere* (2).

Sintering Cycle

A predetermined and closely controlled time-temperature regime for sintering compacts, including the heating and cooling phases.

Sintering Temperature

The maximum temperature at which a powder compact is sintered. The temperature was either measured directly on the surface of the body by optical pyrometer, or indirectly by thermocouples installed in the furnace chamber.

Sintering Time

The time period during which a powder compact is at sintering temperature.

Sintrate

In powder metallurgy, controlled heating so that a compact is sintered before the melting point of an infiltrating material is reached. See also *infiltration*.

Sisal

The hard, strong, light-yellow to reddish fibers from the large leaves of the sisal plant, and the henequen plant. Sisal is employed for making rope, cordage, and sacking. About 80% of all binder twine is normally made from sisal, but sisal ropes have only 75% of the strength of Manila rope and are not as resistant to moisture. Sisal is a tropical plant, and grows best in semiarid regions. **Yucatan sisal**, or **henequen**, is from the henequen plant and is reddish, stiffer, and coarser, and is used for binder twine. The Indian word *henequen* means knife, from the knifelike leaves. The plant is more drought-resistant than sisal.

The fibers of sisal are not as long or as strong as those of Manila hemp, and they swell when wet, and they are soft and are preferred for binder twine either alone or mixed with Manila hemp. **Sisal fiber** is also used instead of hair in cement plasters for walls and in laminated plastics. **Corolite** is a molded plastic made with a mat of sisal fibers so as to give equal strength in all directions. **Tampico**, which yields a stiff, hard, but pliant fiber employed for circular power brushes, is valued for polishing wheels, as the fibers hold the grease buffing composition, and it is not brittle but abrades with flexibility.

Agava, of Agava Products, Inc., is a dark-brown, viscous liquid extracted from the leaves of agave plants, used as a water conditioner for boiler-water treatment. It is a complex mixture of sapogenins, enzymes, chlorophyllin, and polysaccharides.

A fine strong fiber is obtained from the long leaves of the **pine-apple**, native to tropical America. The plant is grown chiefly for its fruit, known in South America under its Carib name **anana'** and marketed widely as canned fruit and juice, preserves, and confections. For fiber production the plants are spaced widely for leaf development and are harvested before the leaves are fully mature. The retted fibers are long, white, and of fine texture and may be woven into water-resistant fabrics. The very delicate and expensive **piña cloth** of the Philippines is made from **pineapple fiber**. The fabrics of Taiwan are usually coarser and harder.

Situ

See *In situ*.

Size

In composites manufacturing, a treatment consisting of starch, gelatin, oil, wax, or other suitable ingredients applied to yarn or fibers at the time of formation to protect the surface and aid the process of handling and fabrication or to control the fiber characteristics. The treatment contains ingredients that provide surface lubricity and binding action, but unlike a finish, contains no coupling agent. Before final fabrication into a composite, the size is usually removed by heat cleaning, and a finish is applied.

Size Effect

Effect of the dimensions of a piece of metal on its mechanical and other properties and on manufacturing variables such as forging reduction and heat treatment. In general, the mechanical properties are lower for a larger size.

Size-Exclusion Chromatography (SEC)

Liquid chromatography method that separates molecules on the basis of their physical size. This technique is most often used in the analysis of polymers. Also termed *gel permeation chromatography*.

Size Factor

The relationship between the size of atoms which determine, in part, how they form solutions and compounds. If atoms of different elements, or more strictly their positive ions, are similar in size then, if other factors are correct, they conform substitutional solid solutions. If they are widely different and other factors are appropriate they may form interstitial solid solutions or compounds. See *solution* and *size factor compounds*.

Size Factor Compounds

These are intermetallic phases formed when the size factor and other aspects are suitable and the elements are present in specific simple proportions. The laves phases are based on the relationship AB_2 , hence $MgCu_2$ or $TiCr_2$, which form when the constituent atoms differ in size by about 22.5% allowing a particular form of close packing. The interstitial compounds form when certain metals and nonmetals having widely differing atomic sizes and so able to adopt an interstitial structure. Examples include carbides such as Fe_3C , WC and Mo_2C or nitrides such as TiN .

Size Fraction

A separated fraction of a powder whose particles lie between specified upper and lower size limits. See also *sieve analysis*.

Size of Weld

(1) The joint penetration in a groove weld. (2) The lengths of the nominal legs of a fillet weld. (3) The weld metal thickness measured at the root of a flange weld.

Sizing (Adhesives)

The process of applying a material on a surface in order to fill pores and thus reduce the absorption of the subsequently applied adhesive or coating or to otherwise modify the surface properties of the substrate to improve the adhesion, and also, the material used for this purpose. See also *primer*.

Sizing (Composites)

See *size*.

Sizing (Metals)

(1) Secondary forming or squeezing operations needed to square up, set down, flatten, or otherwise correct surfaces to produce specified

dimensions and tolerances. See also *restriking*. (2) Burnishing, broaching, drawing, and shaving operations are also called sizing. (3) A finishing operation for correcting ovality in tubing. (4) Final pressing of a sintered powder metallurgy part to obtain a desired dimension.

Sizing Agents

These coatings are applied to glass textile fibers in the forming operation. The sizes use may contain one or more or any combination of binders, lubricants, and coupling agents.

Dextrin

A starch derivative commonly called starch in the fiberglass industry. It is of the low viscosity variety when used in fiberglass sizes. Practically all the fiberglass yarn that has been woven has been sized with this starch size. In industrial fiberglass fabrics, the size is removed in a process called heat cleaning, whereas in decorative woven material the size is burned off in the coronizing operation.

Gelatin

Used in small amounts as a constituent of a standard glass fiber textile size. Together with dextrin (starch), the gelatin acts as a binder for the other materials formulated into a size for the fiberglass textile yarns.

Polyvinyl Acetate

As a latex, it is used as a binder in a standard size formulation for continuous fiberglass yarn. Usually this continuous yarn is made into roving and a large package is usually made up of 60 ends of continuous yarn, although other end counts such as 30 ends, 20 ends, and 8 ends are also available. Roving is used primarily as reinforcement in reinforced plastics, and in preforming operations.

Sizing Content (Composites)

The percent of the total strand weight made up of sizing, usually determined by burning off or dissolving the organic sizing. Also known as loss on ignition. See also *size*.

Sizing Die

A die used for the *sizing* of a sintered compact.

Sizing Punch

A punch used for the pressing of a sintered compact during the *sizing operation*.

Sizing Knockout

An ejector punch used for rejecting a sintered compact from one *sizing die*.

Sizing Pass

The final light working pass in rolling or drawing to provide a high-quality surface with precise dimensions.

S

Sizing Stripper

A punch used during the *sizing* operation.

Skein

A continuous filament, strand, yarn, or roving for reinforced plastics, wound up to some measurable length and usually used to measure various physical properties.

Skeleton

An unsintered or sintered porous powder metallurgy compact with a large proportion of interconnected porosity that makes it suitable for *infiltration*.

Skelp

(1) The starting stock for making welded pipe or tubing, most often it is strip stock of suitable width, thickness, and edge configuration. (2) Slit strip with any edge preparation that is to be formed into a tube by longitudinally rolling and, or drawing through a die prior to seam welding.

Skidding

A form of nonuniform relative motion between solid surfaces due to rapid periodic changes in the traction between those surfaces.

Skid-Polishing Process

A mechanical polishing process in which the surface of the metallographic specimen to be polished is made to skid across a layer of paste, consisting of the abrasive and the polishing fluid, without contacting the fibers of the polishing cloth.

Skim Gate

In foundry practice, a gating arrangement designed to prevent the passage of slag and other undesirable materials into a casting.

Skimmer

A tool for measuring scum, slag, and dross from the surface of molten metal.

Skimming

Removing or holding back dirt or slag from the surface of the molten metal before or during pouring.

Skin (Metals)

A thin outside metal layer, not formed by bonding as in cladding or electroplating, that differs in composition, structure, or other characteristics from the main mass of metal.

Skin (Plastics)

The relatively dense material that sometimes forms on the surface of a cellular plastic or sandwich construction.

Skin Drying

Drying the surface of a foundry mold by direct application of heat.

Skin Effect

Concentration of material.

Skin Lamination

In flat-rolled metals, a surface rupture resulting from the exposure of a subsurface lamination by rolling.

Skin Pass

The confinement of high-frequency electrical currents to the skin, i.e., outer surface, of a conductor. See *temper rolling*.

Skip Sequence Weld

A welding technique in which a long run of weld is built up by a number of short deposits laid in a preplanned sequence such that the first series of welds are made with gaps between them and subsequent welds fill the gaps.

Skip Weld

See preferred term *intermittent weld*.

Skiving

(1) Removal of a material in layers or chips with a high degree of sheer or slippage, or both, of the cutting tool. (2) A machining operation in which the cut is made with a form tool with its face so angled that the cutting edge progresses from one end of the work to the other as the tool feeds tangentially past the rotating workpiece.

Skull

(1) A layer of solidified metal or dross on the walls of a pouring vessel after the metal has been poured. (2) The unmelted residue from a liquated weld filler metal.

Slab

(1) A flat-shaped semifinished rolled metal ingot with a width not less than 250 mm (10 in.) and a cross-sectional area not less than 105 cm³ (16 in.³). (2) An imprecise term referring to part rolled material with a thickness about half its width. It is implicit that it will subsequently be rolled to plate or sheet.

Slabbing

The hot working of an *ingot* to a flat rectangular shape.

Slabbing Mill

See preferred term *peripheral milling*.

Slack Quenching

The incomplete hardening of steel due to quenching from the austenitizing temperature at a rate slower than the critical cooling rate for the particular steel, resulting in the formation of one or more transformation products in addition to martensite. Cooling steel at a rate insufficient to form a fully martensitic structure but fast enough to form bainite. See *steel*.

Slag

(1) A nonmetallic product resulting from the mutual dissolution of flux and nonmetallic impurities in smelting, refining, and certain welding operations (see, for example, *electroslag welding*). In steel-making operations, the slag serves to protect the molten metal from the air and to extract certain impurities. (2) The mixture of flux and impurities extracted from the metal, which warms during various smelting processes. It floats on, and remains separate from, the underlying metal and has the additional benefit in some cases that it protects the underlying metal from the environment.

The molten material that is drawn from the surface of iron in the blast furnace. Slag is formed from the earthy materials in the ore and from the flux. Slags are produced in the melting of other metals, but iron blast-furnace slag is usually meant by the term. Slag is used in cements and concrete, for roofing, and as a ballast for roads and railways. Finely crushed slag is used in agriculture for neutralizing acid soils. **Blast-furnace slag** is one of the lightest concrete aggregates available. It has a porous structure and, when crushed, is angular. It is also crushed and used for making pozzuolana and other cements. Slag contains about 32% silica, 14% alumina, 47% lime, 2% magnesia, and small amounts of other elements. It is crushed, screen, and graded for marketing. **Crushed slag** is about 30% lighter than gravel. **Honeycomb slag** is the finest grade of commercial slag is from 0.48 cm to dust; the run-of-crusher slag is from 10 cm to dust. **Basic phosphate slag**, a by-product in the manufacture of steel from phosphate ores, is finely ground and sold for fertilizer. It contains not less than 12% phosphoric oxide, P_2O_5 , and is known in Europe as **Thomas slag**. **Foamed slag** is a name used in England for honeycomb slag used for making lightweight, heat-insulating blocks. A superphosphate cement is made in Belgium from a mixture of basic slag, slaked lime, and gypsum.

Slag Fiber/Wool

Fine stranded fibers formed from various slags and similar in texture to glass wool or fiber. It commonly substitutes for the glass product as an insulating material.

Slag Inclusion

(1) Slag or dross entrapped in a metal. (2) Nonmetallic solid material entrapped in weld metal or between weld metal and base metal.

Slag Trap (of Weld Joint)

Any joint geometry or feature which could retain molten slag and impede its subsequent removal.

Slant Fracture

A type of fracture in metals, typical of *plane-stress* fractures, in which the plane of separation is inclined at an angle (usually about 45°) to the axis of applied stress.

Slate

A shale having a straight cleavage. Most shales are of sedimentary origin, and their cleavage was the result of heavy or long-continued pressure. In some cases slates have been formed by the consolidation of volcanic ashes. The slaty cleavage does not usually coincide with the original stratification. Slate is of various colors: black, gray, green, and reddish. It is used for electric panels, chalkboards, slate pencils, tabletops, roofing shingles, floor tiles, and treads. The terms **flagstone** and **cleftstone** are given to large, flat sections of slate used for paving, but the names are also applied to blue sandstones cut for this purpose. Slate is quarried in large blocks, and then slabbed and split. The chief slate producing states are Pennsylvania, Vermont, Virginia, New York, and Maine. Roofing slates vary in size from 30 × 15 cm to 61 × 36 cm, and from 0.32 to 1.91 cm in thickness, and are usually of the harder varieties. The roofing slate from coal beds is black, fine-grained, and breaks into brittle thin sheets. It does not have the hardness or weather resistance of true slate. **Ribbon slate**, with streaks of hard material, is inferior for all purposes. Lime impurities can be detected by the application of dilute hydrochloric acid to the edges and noting if rapid effervescence occurs. Iron is a detriment to slates for electric purposes. **Slate granules** are small, graded chips used for surfacing prepared roofing. **Slate flour** is ground slate, largely a by-product of granule production. It is used in linoleum, caulking compounds, and asphalt surfacing mixtures. **Slate lime** is an intimate mixture of finely divided, calcined slate and lime, about 60% by weight lime to 40 slate. It is employed for making porous concrete for insulating partition walls. The process consists in adding a mixture of slate lime and powdered aluminum, zinc, or magnesium to the cement. The gas generated on the addition of water makes the cement porous.

Sleeve Bearing

A cylindrical plain bearing used to provide radial location for a shaft, which moves axially. Sleeve bearings usually consists of one or more layers of bearing alloy(s), or liner, bonded to a steel backing. Sleeve bearing is sometimes used to denote *journal bearing*. See also *sliding bearing*.

Slice

The cross-sectional plane through an object that is scanned to produce the image in *computed tomography*. See also *tomographic plane*.

Slices

Sections of ingots of single-crystal material that have been sawed from the ingot. Also known as wafers.

Slide

The main reciprocating member of a metal forming press, guided in the press frame, to which the punch or upper die is fastened; sometimes called the *ram*. The inner slide of a double-action press is called the plunger or punch-holder slide; the outer slide is called the blank-holder slide. The third slide of a triple-action press is called the lower slide, and the slide of a hydraulic press is often called the platen. See also the term *press forming* and *straight-side press*.

S

Slide Adjustment

The distance that a metal forming press slide position can be altered to change the shut height of the die space. The adjustment can be made by hand or by power mechanism.

Slide-Roll Ratio

See *slide-sweep ratio*.

Slide-Sweep Ratio

The ratio of sliding velocity to sweep velocity, for example, in a pair of gears. In rolling, the slide-sweep ratio is called the *slide-roll ratio*.

Sliding (Pure Sliding with no Rolling or Spin)

A motion of two relatively moving bodies, in which their surface velocities in the common contact area are different with regard to magnitude and/or direction. See also *rolling*, *spin*, and *specific sliding*.

Sliding Bearing

A bearing in which predominately sliding contact occurs between relatively moving surfaces. Sliding bearings may be either unlubricated, liquid lubricated, grease lubricated, or solid lubricated. See also *sleeve bearing*.

Sliding Fit

A fit with just sufficient slack to allow the mating components to move axially relative to each other without galling but without perceptible lateral play. This usually implies an interfacial gap just sufficient to accommodate a film of lubricant. Contrast with *push fit*. Similar to *slip fit*.

Sliding Velocity

The difference between the velocities of each of the two surfaces relative to the point of contact.

Slime

(1) A material extremely fine particle size encountered in ore treatment. (2) A mixture of metals and some insoluble compounds that forms on the anode in electrolysis.

Slip

(1) Deformation by planes of atoms in the crystal lattice sliding over each other. The sliding action is facilitated by the movement of dislocations. (2) The thick water-based paste used in slip casting.

Slip (Adhesives)

In an adhesively bonded components or specimens, the relative col-linear displacement of the adherends on either side of the adhesive layer in the direction of the applied load.

Slip (Ceramics)

(1) A slurry or suspension of fine clay or other ceramic powders in water, having the consistency of cream, that is used in slip casting or as a cement or glass preparation. (2) A suspension of colloidal powder in an immiscible liquid (usually water).

Slip (Metals)

Plastic deformation by the irreversible shear displacement (translation) of one part of a crystal relative to another in a definite crystallographic direction and usually on specific crystallographic plane. Sometimes called glide.

Slip Angle

The angle at which a tensioned fiber will slide off a filament-wound dome. If the difference between the wind angle and the geodesic angle is less than the slip angle, the fiber will not slide off the dome. Slip angles for different fiber-resin systems vary and must be determined experimentally. See also *filament winding* and *wind angle*.

Slip Band

A group of parallel slip lines so closely spaced as to appear as a single line when observed under an optical microscope. See also *slip line*.

Slip Casting

(1) The ceramic forming process consisting of filling or coating a porous mold with a *slip*, allowing to dry, and removing for subsequent firing. (2) A technique in which a water and powder paste is poured into an absorbent plaster mold. The mold absorbs most of the water leaving a fragile replica of the mold interior.

Slip Coating

A ceramic material or mixture other than a glaze, applied to a ceramic body and fired to the maturity required to develop specified characteristics.

Slip Crack

See *pressing crack*.

Slip Direction

The crystallographic direction in which the translation of slip takes place. See the term *slip* (metals).

Slip Fit

A loosely defined *clearance fit* between parts assembled by hand without force, but implying slipping contact.

Slip Flask

A tapered *flask* that depends on a movable strip of metal to hold foundry sand in position. After closing the mold, the strip is

refracted and the flask can be removed and reused. Molds thus made are usually supported by a *mold jacket* during pouring.

Slip Forming

A plastic sheet-forming technique in which some of the sheet material is allowed to slip through the mechanically operated clamping rings during a stretch-forming operation.

Slip-Interference Theory

Theory involving the resistance to deformation offered by a hard phase dispersed in a ductile matrix.

Slip Liner

(1) Visible traces of slip planes on metal surfaces; the traces are (usually) observable only if the surface has been polished before deformation. The usual observation on metal crystals (under a light microscope) is of a cluster of slip lines known as a *slip band*. (2) Markings produced on deformed surfaces that were polished prior to deformation. They arise because neighboring areas have deformed along differently aligned slip planes giving rise to surface irregularities.

Slippage

The movement of the adherends with respect to each other during the adhesive bonding process.

Slip Plane

The crystallographic plane in which *slip* occurs in a crystal.

Slitting

Cutting or shearing along single lines to cut strips from a metal sheet or to cut along the lines of a given length or contour in a sheet or workpiece.

Sliver (Composites)

A number of staple or continuous filament fibers are aligned in a continuous strand without twist. See also *continuous filament yarn*, *staple fiber*, and *strand*.

Sliver (Metals)

An imperfection consisting of a very thin elongated piece of metal attached by only one end to the parent metal into whose surface it has been worked.

Slope Control

Producing electronically a gradual increase or decrease in the welding current between definite limits and within a selected time interval.

Slot Extrusion

A method of extruding plastic film or sheet in which the molten thermoplastic compound is forced through a slot die (T-shaped or coat

hanger shape). Following extrusion, the film or sheet is cooled by passing it through a water bath or over water-cooled rolls.

Slot Furnace

A common batch furnace for heat treating metals where stock is charged and removed through a slot or opening.

Slotting

Cutting a narrow aperture or groove with a reciprocating tool in a vertical shaper or with a cutter, broach, or grinding wheel.

Slot Weld

A weld made in an elongated hole in one member of a lap or T-joint joining that member to that portion of the surface of the other member which is exposed through the hole. The hole may be open at one end and may be partially or completely filled with weld metal. A fillet welded slot should not be construed as conforming to this definition.

Slow Bend Test

A bend test to determine the ductility/brittleness characteristics of metals, usually steel. The term contrast with the fast loading rate of impact tests for determining such characteristics. The test specimen may be notched or plain and may be loaded in either three-point or four-point bending.

Slow Butt Welding

Same as *resistance butt welding*.

Slow Strain Rate Technique

An experimental technique for evaluating susceptibility to *stress-corrosion cracking*. It involves pulling the specimen to failure in uniaxial tension at a controlled slow strain rate while the specimen is in the test environment and examining the specimen for evidence of stress-corrosion cracking.

Sludge

A coagulated mass, often containing foreign matter, formed at low temperature in combustion engines from oil oxidation residues, carbon, and water.

Sluffing

An occurrence during protrusion of reinforced plastics in which scales peel off or become loose, either partially or entirely, from a pultrusion. Not to be confused with scraping, prying, or physically removing scale from a pultrusion. Sluffing is sometimes spelled sloughing. See also *pultrusion*.

Slug

(1) A short piece of metal to be placed in a die for forging or extrusion. (2) A small piece of material produced by piercing a hole in sheet material. See also *blank*.

S

Slug Test

Same as *peel test*.

Slugging

The unsound practice of adding a separate piece of material in a joint before or during welding, resulting in a welded joint in which the weld zone is not entirely built up by adding molten filler metal or by melting and recasting base metal, and which therefore does not comply with design, drawing, or specification requirements. Such material partly fills the joint and is hidden by subsequently deposited weld metal but is not fully fused and forms a serious weakness.

Slumpability

The flow of gravity of a grease in a container, allowing it to feed out into a pump or can. Slumpability also influences the leakage of grease from a bearing.

Slurry

(1) A thick mixture of liquid and solids, the solids being in suspension in the liquid. (2) Any pourable or pumpable suspension of a high content of insoluble particulate solids in a liquid medium, most often water. (3) The thick suspension of solids in water or other liquid is less viscous than a paste and easily poured. See also *slip*.

Slurry Abrasion Response (SAR) Number

A measure of the relative abrasion response of any material in any slurry, as related to the instantaneous rate of mass loss of a specimen at a specific time on the cumulative abrasion-corrosion time curve, converted to volume or thickness loss rate. See also *Miller number*.

Slurry Abrasivity

The relative tendency of a particular moving slurry to produce abrasive and corrosive wear compared with other slurries.

Slurry Erosion

Erosion produced by the movement of a slurry past a solid surface.

Slurry Preforming

Method of preparing a reinforced plastic preforms by wet processing technique similar to those used in the pulp molding industry. For example, glass fibers suspended in water are passed through a screen that passes the water but retains the fibers in the form of a mat.

Slush

Material in an intermediate stage between fully molten and fully solid.

Slush Casting/Molding

(1) A technique for producing hollow castings. Molten metal is poured into a mold, usually metal and often of complex shape. The molten metal is usually swirled round and, after a solid skin has

formed over the mold interior, the remaining molten metal is poured out. In a variation on the process a measured amount of molten metal is introduced through an orifice which is then sealed prior to swirling. In this way a fully enclosed hollow is produced. (2) Processes in which the alloy is poured or injected in a pasty, partly solidified, state. See *rheocasting*.

Slushing Compound

An obsolete term for describing oil or grease coatings used to provide temporary protection against *atmospheric corrosion*.

Slushing Oil

A mineral oil containing additives that enable it to protect the parts of a machine against rusting.

Slush Molding

A method for casting thermoplastics, in which the resin in liquid form it is poured into a hot mold where a viscous skin forms. The excess slush is drained off, the mold is cooled, and the molding stripped out.

SMC

See *sheet molding compound*.

SME

Shape memory effect.

Smart Materials

Materials which alter some significant characteristic when subjected to some external stimulus, for example, piezoelectric crystals which generate a voltage when stressed.

Smearing

Mechanical removal of material from a surface, usually involving plastic shear deformation, and redeposition of the material as a thin layer on one or both surfaces. See also *transfer*.

Smelting

(1) Thermal processing wherein chemical reactions take place to produce liquid metal from a beneficiated ore. (2) Processes involving chemical reaction at high temperatures to reduce ore to molten metal or to some intermediate product. Where the final product is to be molten metal a flux is usually added to combine with the unwanted oxide and other impurities forming a slag.

Smith Forging

See *hand forge (smith forge)*.

Smoke

Airborne finely particulate materials usually products of combustion.

Smoke Agents

Chemicals used in warfare to produce an obscuring cloud of fog to high movements. Smokes may be harmless and are then called **screening smokes**, or **smoke screens**, or they may be toxic and called **blanketing clouds**. There are two types of smokes: those forming solid or liquid particles and those forming fogs or mists by chemical reaction. **White smokes**, which do not have light-absorbing particles, such as carbon, are formed by chemical reaction and have the best opacity or screening action. The first Naval smoke screens were made by limiting the admission of air to the fuel in the boilers, and the first Army smoke pots contained mixtures of pitch, tallow, saltpeter, and gunpowder. The British **smoke candles** contained 40% potassium nitrate, 29% pitch, 14% sulfur, 8% borax, and 9% coal dust. They gave a brown smoke, but one that lifted too easily.

Fog or military screening may be made by spraying an oil mixture into the air at high velocity. The microscopic droplets produce an impenetrable fog which remains for long period. **White phosphorus** is a dense, white smoke, called **WP smoke**, by burning to the pentoxide and changing to phosphoric acid in the moisture of the air. Its vapor is toxic. Smoke from **red phosphorus** is known as **RP smoke**. **Sulfuric trioxide**, SO_3 , is an effective smoke producer in humid air. It is a mobile, colorless liquid vaporizing at 45°C to form dense, white clouds with an irritating effect. The French **opacite** is **tin tetrachloride** or **stannic chloride**, SnCl_4 , a liquid that fumes in air. The smoke is not dense, but it is corrosive and it penetrates gas masks. **FS smoke** is made with a mixture of chlorosulfonic acid and sulfur trioxide. **Silicon tetrachloride**, SiCl_4 , is a colorless liquid that boils at 60°C , and fumes in the air, forming a dense cloud. Mixed with ammonia vapor, it resembles a natural fog. The heavy mineral known as **amang**, separated from Malayan tin ore, containing ilmenite and zircon, is used for smoke screens. **Titanium tetrachloride**, TiCl_4 , is a colorless to reddish liquid boiling at 136°C . It is used for smoke screens and for skywriting from airplanes. In most air it forms dense, white fumes of **titanic acid**, and hydrogen chloride. The commercial liquid contains about 25% titanium by weight.

A common smoke for airplanes is **oleum**. It is a mixture of sulfur trioxide in sulfuric acid, which forms fuming sulfuric acid, or **pyrosulfuric acid**. The dense liquid is squirted in the exhaust manifold. **Zinc smoke** is made with mixtures of zinc dust or zinc oxide with various chemicals to form clouds. **HC smoke** is zinc chloride with an oxidizing agent to burn up residual carbon so that the smoke will be gray and not black. **Signal smoke** is colored smoke used for ship distress signals and for radiation marking signals. They are mixtures of a fuel, an oxidizing agent, a dye, and sometimes a cooling agent to regulate the rate of burning and to prevent decomposition of the dye. Unmistakable colors are used so that the signals may be distinguished from fires, and the dyes are mainly anthraquinone derivatives, together with mixtures of an azo, azine, and diphenyl-methane compounds.

Smut

(1) A reaction product sometimes left on the surface of a metal after pickling, electroplating, or etching. (2) Finely particulate material released into the atmosphere usually as a result of combustion. (3) Surface blackening produced on some metals by pickling in caustic soda solution.

Snagging

(1) Heavy stock removal of superfluous material from a workpiece by using a portable or swing grinder mounted with a coarse grain

abrasive wheel. (2) *Offhand grinding* on castings and forgings to remove surplus metal such as gate and riser pads, fins, and parting lines.

Snake

(1) The product formed by twisting and bending of hot metal rod prior to its next rolling process. (2) Any crooked surface imperfection in a plate, resembling a snake. (3) A flexible mandrel used in the inside of a shape to prevent flattening or collapse during a bending operation.

Snakeskins

The snakeskins employed for fancy leathers are in general the skins of large, tropical snakes which are notable for the beauty or oddity of their markings. Snakeskins for shoe-upper leathers, belts, and handbags are glazed like kid and calfskin after tanning. Small cuttings are used for inlaying on novelties. The leather is very thin, but is remarkably durable and is vegetable-tanned and finished in natural colors, or is dyed. **Python skins** are used for ladies' shoes. Diamond-backed rattlesnakes are raised on snake farms in the United States. The meat is canned as food, and the skins are tanned into leather. Only the back is used for leather, as the belly is colorless.

Snaky Edges

See *carbon edges*.

Snap Flask

A foundry flask hinged on one corner so that it can be opened and removed from the mold for reuse before the metal is poured.

Snap Temper

A precautionary interim stress-relieving treatment applied to high-hardenability steels immediately after quenching to prevent cracking because of delay and tempering them at the prescribed higher temperature.

S-N Curve

A plot of stress (S) against the number of cycles to failure (N). The stress can be the maximum stress ($S_{\max}$) or the alternating stress amplitude (S_a). The stress values are usually nominal stress; i.e., there is no adjustment for stress concentration. The diagram indicates the S - N relationship for a specified value of the mean stress (S_m) or the stress ratio (A or R) and a specified probability of survival. For N a log scale is almost always used. For S a linear scale is used most often, but a log scale is sometimes used. Also known as S - N diagram.

S-N Curve for 50% Survival

A curve fitted to the median value of fatigue life at each of several stress levels. It is an estimate of the relationship between applied stress and the number of cycles-to-failure that 50% of the population would survive.

S

S-N Curve for $p\%$ Survival

A curve fitted to the fatigue life for $p\%$ survival values at each of several stress levels. It is an estimate of the relationship between applied stress and the number of cycles-to-failure that $p\%$ of the population would survive. p may be any number, such as 95, 90, etc.

Snowflakes

See *flakes*.

Snug Fit

A loosely defined fit implying the closest clearances that can be assembled manually for firm connection between parts. See also *clearance fit*.

Soak Cleaning

Immersion cleaning without electrolysis.

Soaking

In heat treating of metals, prolonged holding at a selected temperature to effect homogenization of structure or composition. See also *homogenizing*.

Soaking Pit

A chamber in which newly cast ingots, particularly steel, are stored to allow the temperature to equalize prior to the first hot rolling operation. There may also be some homogenization of the structure. The facility may be no more than an insulated but unheated hole in the ground usually with some form of copper but supplementary heating may be applied.

Soak Time

The length of time a ceramic material is peanut at the peak temperature of the firing cycle. See also *firing*.

Soap

In lubrication, a compound formed by the reaction of a fatty acid with a metal or metal compound. Metallic soaps formed by reaction *in situ* are an important group of boundary lubricants.

A cleansing compound produced by saponifying oils, fats, or grease with an alkali. When caustic soda is added to fat, glycerin separates out, leaving **sodium oleate**, which is soap. But since oils and fats are mixtures of various acid glycerides, the soaps made directly from vegetable and animal oils may be mixtures of oleates, palmitates, linoleates, and laurates. **Soap oils** in general, however, are those oils which have greater proportions of nearly saturated fatty acids, since the unsaturated fractions tend to oxidize to form aldehydes, ketones, or other acids, and turn rancid. If an excess of alkali is used, the soap will contain free alkali; and the greater the portion of the free alkali, the coarser is the action of the soap. ASTM standards for milled toilet soap permit only 0.17% free alkali. Soap makers now employ refined and bleached oils, which are then hydrolyzed into fatty acids and glycerol prior to saponification with caustic. This allows the fatty acids to be distilled, resulting in a more stable product. **Sodium soaps** are always harder than **potassium**

soaps with the same fat or oil. Hard sodium soaps are used for chips, powders, and toilet soaps. Soft, caustic potash soaps are the liquid, soft, and semi soft pastes. Mixtures of the two are also used. Soaps are made by either the boiled process or the cold process. Chip soap is made by pouring the hot soap onto a cooled revolving cylinder from which the soap is scraped in the form of chips or ribbons which are then dried to reduce the moisture content from 30% to 10%. Soap flakes are made by passing chips through milling rollers to make thin, polished, easily soluble flakes.

Powdered soap is made from chips by further reducing the mixture and grinding. **Milled soaps** are made from chips by adding color and perfumes to the dry chips and then passing through milling rollers and finally pressing in molds. **Toilet soaps** are made in this way. Soap is used widely in industrial processing, and much of the production has consisted of chips, flakes, powdered, granulated, and scouring powders. Soaps have definitely limitations of use. They are unstable in acid solutions and may form insoluble salts. In hard waters they may form insoluble soaps of calcium or magnesium unless a phosphate is added. Many industrial cleansers, therefore, may be balanced combinations of soaps, synthetic detergents, phosphates, or alkalies, designed for particular purposes.

About half of all soap is made with tallow, 25% with coconut oil, and the remainder with palm oil, greases, fish oils, olive oil, soybean oil, or mixtures. A typical soap contains 80% mixed oils and 20 coconut oil, with not over 0.2 free alkali. Auxiliary ingredients are used in soap to improve the color, for perfuming, as an astringent, or for abrasive or harsh cleaning purposes. Phenol or cresylic acid compounds are used in **antiseptic soap**. The soft soaps and liquid soaps of USP grade have a therapeutic value and may be sold under trade names.

Solvents are added to industrial soaps for scouring textiles or when used in soluble oils in the metal industry. Zinc oxide, benzoic acid, and other materials are used in facial soaps with the idea of aiding complexion. Excessive alkalinity in soaps dries and irritates the skin, but **hand grit soap** usually has 2%–5% alkaline salts such as borax or soda ash and 10%–25% abrasive materials. Softer **hand soap** may contain marble flour. Silicate of soda, used as a filler, also irritates the skin. **Face soaps**, or **toilet soaps**, contain coloring agents, stabilizers, and perfuming agents. For special purposes, **cosmetic soaps** contain medications. **Deodorant soaps** contain antibacterial chemicals, such as **triclosan**, which inhibit the production of bacteria on the skin. Experts disagree on whether antibacterial ingredients are harmful to the skin. Some, such as **Dove**, are a blend of detergents and soap. **Castile soap** is a semitransparent soap made with olive oil. **Marseilles soap** and **Venetian soap** are names for castile soap with olive oil and soda. Ordinary soft soaps are used as bases for toilet soap are made with mixtures of linseed oil and olive oil. Linseed oil, however, gives a disagreeable odor. Soybean oil, corn oil, and peanut oil are also used, although peanut oil, unless the arachidic acid is removed, makes a hard soap. **Tall oil soaps** are sodium soaps made from the fatty acids of tall oil. They are inferior to sodium oleate in detergency, but superior to sodium rosinate. Many toilet soaps contain excess unsaponified oil, fatty acid, or lanolin and are known as **superfatted**.

Saddle soap is any soap used for cleaning leather goods which has the property of filling and smoothing the leather as well as cleaning. The original saddle soaps were made of palm oil, rosin, and lye, with glycerin and beeswax added. Oils for the best soaps are of the nondrying type. High-grade **soft soap** for industrial use is made with coconut or palm kernel oil with caustic potash. But soft soap in paste form is generally made of low-titer oils with caustic soda, usually linseed, soybean, or corn oil. The lauric acid of coconut oil gives the coconut-oil soaps their characteristic of profuse

lathering, but lauric acid affects some skins by causing itching, and soaps when a high-coconut-oil content and low titer are also likely to break down in hot water and wash ineffectively. Palm-kernel oil develops free acids, and upon aging the soap acquires the odor of the oil. Palm oil produces a crumbly soap. It does not lather freely, but is mild to the skin. Olive oil is slow-lathering, but has good cleansing powers. It is often used in textile soaps. Cottonseed oil is used in some laundry soaps but develops yellow spots in the soap. Corn oil with potash makes a mild soft soap. Soybean oil also makes a soft soap. Rosin is used to make yellow laundry soaps. ASTM standards for **bar soap** permit up to 25% rosin. Sulfonated oils do not give as good cleansing action as straight oils, but are used in shampoos where it is desirable to have some oil or greasiness. Blending of various oils is necessary to obtain a balance of desired characteristics in a soap. Hand soaps may be made with trisodium phosphate or with disodium phosphate, or sodium perborate, known as **per-borin**, all of which are crystalline substances which are dissolved in water solution. **Soap powder** is granular soap made in a vacuum chamber or by other special processes. It usually contains 15%–20% soap and the balance sodium carbonate. **Scouring powder** is an intimate mixture of soap powder and in insoluble abrasives such as pumice. **Floating soaps** are made light by blowing air through them while in the vats. **Soapless shampoos** and tooth powders contain saponin or chemical detergents. **Liquid soaps** are made by saponification with potassium and ammonium hydroxide, or triethanolamine, to produce more-soluble products. The floating soaps, such as **Ivory** from Proctor & Gamble Co., are made by injecting air into the molten soap.

Soapstone

The bulk form of talc, also termed steatite, hydrated magnesium silicate. A very soft mineral, it is No. 1 on the Mohs scale of hardness. It has a high electrical resistance and is hence used for insulators. It is readily carved for ornamental applications. In powder form it is termed *French Chalk* or, if perfumed, *Talcum Powder*.

A massive variety of impure talc is employed for electric panels, gas-jet trips, stove linings, tank linings, and as an abrasive. It can be cut easily and becomes very hard when heated because of the loss of its combined water. The waste product from the cutting of soapstone is ground and used for the same purposes as talc powder. **Steatite** is a massive stone rich in talc that can be cut readily, while soapstone may be low in talc. When free of iron oxide and other impurities, blocks of steatite are used for making spacer insulators for electronic tubes and for special electrical insulators. **Block steatite** suitable for electrical insulation is mined in Montana, India, and Sardinia. Steatite is also ground and molded into insulators. It can be purified of iron and other metallic impurities by electrolytic osmosis. When fluxed with alkaline earths instead of feldspar, the molded steatite ceramics have a low loss factor at high frequencies, and have good electrical properties at high temperatures. **Talc crayons** for marking steel are sticks of soapstone.

Soda Ash

Sodium carbonate (Na_2CO_3) obtained from trona, a hydrated sodium carbonate sodium bicarbonate ore. Soda ash is used in petroleum refining and for soaps and detergents. Its primary use, however, is in glass manufacture. Soda ash is the third major constituent of soda-lime-silica glasses and is the main source of Na_2O in any glass that contains soda. It acts as a flux, reducing the temperature required to melt the silica. See also *Solvay process*.

The common name for anhydrous **sodium carbonate**, which is the most important industrial alkali. It is a grayish-white, lumpy material which loses any water of crystallization when heated. For household used in hydrous crystallize form it is called **washing soda**, **soda crystals**, or **sal soda**, as distinct from **baking soda**, which is **sodium hydrogen carbonate**, or **sodium bicarbonate**. Sal soda contains more than 60% water. Another grade, with one molecule of water, is the standard product for scouring solutions. Federal specifications call for this product to have a total alkalinity not less than 49.7% Na_2O . Commercial high-quality soda ash contains 99% minimum sodium carbonate, or 58 minimum Na_2O . It varies in size of particle and in bulk density, being marketed as extra-light, light, and dense. **Laundry soda** is soda ash mixed with sodium bicarbonate, with 39%–43% Na_2O . **Modified sodas**, used for cleansing where a mild detergent is required, are mixtures of sodium carbonate and sodium bicarbonate. They are used in both industrial and household cleaners. **Tanners' alkali**, used in processing fine leathers, and **textile soda**, used in fine wool and cotton textiles, are modified sodas. **Flour bland**, used by the milling industry in making free-flowing, self-raising food flours, is a mixture of sodium bicarbonate and tricalcium phosphate.

Soda ash is made by the Solvay process, which consists of treating a solution of common salt with ammonia and with carbon dioxide and calcining the resulting filter cake of sodium bicarbonate to make **light soda ash**. **Dense soda ash** is then made by adding water and recalcining. Soda ash is less expensive than caustic soda and is used for cleansing, for softening water, in glass as a flux and to prevent fogging, in the wood-pulp industry, for refining oils, and soap-making, and for the treating of ores. **Caustic ash**, a strong cleaner for metal scouring and for paint removal, is a mixture of about 70% caustic soda and 30% soda ash. **Flake alkali**, of PPG Industries, contains 71% caustic soda and 29% soda ash. Soda ash is also used as a flux in melting iron to increase the fluxing action of the limestone, as it will carry off 11% sulfur in the slag. **Soda briquettes**, used for desulfurizing iron, are made of soda ash formed into pellets with a hydrocarbon bond. **Hennig purifier** is soda ash combined with other steel-purifying agents made into pellets.

The salt brine of Owens Lake, California, is an important source of soda ash. The brine, which contains 10.5% sodium carbonate and 2.5% **sodium borate decahydrate**, is concentrated and treated to precipitate the **trona** (Na_2CO_3). The Salt Lake area of Utah is a source of trona. Soda ash and sodium carbonate may be sold under trade names, **Purite** is a sodium carbonate. **Tronacarb** is an industrial grade, and **Tronalight**, as the name suggests, is a light soda ash.

Soderberg Diagram

See *fatigue*.

Sodium

A metallic element (symbol Na and atomic weight 23), sodium occurs naturally only in the form of its salts. The most important mineral containing sodium is the chloride, NaCl , which is common salt. It also occurs as the nitrate, Chile salt-peter, as a borate in borax, and as a fluoride and a sulfate. When pure, sodium is silvery white and ductile, and it melts at 97.8°C and boils at 882°C . The specific gravity is 0.97. It can be obtained in metallic form by the electrolysis of salt. When exposed to the air, it oxidizes rapidly, and must therefore be kept in airtight containers. It has a high affinity for oxygen, and it decomposes water violently. It also combines directly with

S

the halogens, and is a good reducing agent for the metal chlorides. Sodium is one of the best conductors of electricity and heat.

The metal is a powerful desulfurizer of iron and steel even in combination. For this purpose it may be used in the form of soda ash pellets or in alloys. Desulfurizing alloys for brasses and bronzes are sodium–tin, with 95% tin and 5% sodium, or sodium–copper. Sodium–lead, used for adding sodium to alloys, contains 10% sodium, and is marketed as small spheroidal shot. It is also marketed as **sodium marbles**, which are spheres of pure sodium up to 2.54 cm in diameter coated with oil to reduce handling hazard.

Sodium bricks contain 50% sodium metal powder dispersed in a paraffin binder. They can be handled in the air, and are a source of active sodium. Sodium in combination with potassium is used as a heat-exchange fluid in reactors and high-temperature processing equipment. A sodium–potassium alloy, containing 56% sodium and 44% potassium, has a melting point of 19°C and a boiling point of 825°C. It is a silvery mobile liquid. High-surface sodium is sodium metal absorbed on common salt, alumina, or activated carbon to give a large surface area for use in the reduction of metals or in hydrocarbon refining. Common salt will adsorb up to 10% of its weight of sodium in a thin film on its surface, and this sodium is 100% available for chemical reaction. It is used in reducing titanium tetrachloride to titanium metal. Sodium vapor is used in electric lamps. When the vapor is used with a fused alumina tube it gives a golden-white color. A 400 W lamp produces 42,000 lumens and retains 85% of its efficiency after 6,000 h.

Inorganic Reactions

Sodium reacts rapidly with water, and even with snow and ice, to give sodium hydroxide and hydrogen. The reaction liberates sufficient heat to melt the sodium and ignite the hydrogen.

When exposed to air, freshly cut sodium metal loses its silvery appearance and becomes dull gray because of the formation of a coating of sodium oxide. Sodium probably oxidizes to the peroxide, Na_2O_2 , which reacts with excess sodium present to give the monoxide, Na_2O . When sodium reacts with oxygen at elevated temperatures, sodium super oxide, NaO_2 , is formed; this reacts with more sodium to form the peroxide.

Sodium does not react with nitrogen, even at very high temperatures. Sodium and hydrogen react above about 200°C to form sodium hydroxide. This compound decomposes at about 400°C and cannot be melted. Sodium hydride can be formed by the direct reaction of hydrogen and molten sodium or by hydrogenating dispersions of sodium metal in hydrocarbons. Sodium reacts with carbon with difficulty, if at all, and this reaction may be said to have been adequately studied.

At room temperature fluorine and sodium ignite, dry chlorine and sodium react slightly, bromine and sodium do not react, and iodine and sodium do not react. However, in the presence of moisture or at elevated temperatures all reactions take place at very high rates.

Sodium reacts with ammonia, forming sodium amide and liberating hydrogen. The reaction may be carried out between molten sodium and gaseous ammonia (–30°C) in the presence of catalysts of finely divided metals. Sodium reacts with ammonia in the presence of coke to form sodium cyanide.

Carbon monoxide reacts with sodium, but the resulting carbonyl, NaCO , is stable only at liquid ammonia temperatures. At high temperatures sodium carbide and sodium carbonate are formed from carbon monoxide and sodium.

The reactions of sodium with various metal halides to give the metal plus sodium chloride are very important. Thus, titanium

tetrachloride is reduced to titanium metal. Similarly, the halides of zirconium, beryllium, and thorium can be reduced to the corresponding metals by sodium. The interaction between sodium and potassium chloride is used in the commercial production of potassium metal.

Sodium hydroxide, NaOH , is also commonly known as caustic soda, and also as sodium hydrate. Lye is an old name used in some industries and in household uses. It readily absorbs water from the atmosphere and must be protected in storage and handling. It is corrosive to the skin and must be handled with extreme care to avoid caustic burns.

Most sodium hydroxide is produced by the electrolysis of sodium chloride solutions in one of several types of electrolytic cells. An older process is the soda-lime process whereby soda ash is converted to caustic soda.

Organic Reactions

Sodium does not react with paraffin hydrocarbons but does form additional compounds with naphthalene and other polycyclic aromatic compounds and with arylated alkenes. It reacts with acetylene, replacing the acetylenic hydrogens to form sodium acetylides. Sodium adds to dienes, the reaction which forms the basis of the buna synthetic rubber process.

Principal Compounds

Sodium compounds are widely used in industry, particularly sodium chloride, sodium hydroxide, and soda ash. Sodium bichromate, $\text{Na}_2\text{Cr}_2\text{O}_7 \cdot 2\text{H}_2\text{O}$, a red crystalline powder, is used in leather tanning, textile dyeing, wood preservation, and in pigments. Sodium metavanadate, NaVO_3 , is used as a corrosion inhibitor to protect some chemical-processing piping. It dissolves in hot water, and a small amount in the water forms a tough impervious coating of magnetic iron oxide on the walls of the pipe. Sodium iodide crystals are used as scintillation probes for the detection and analysis of nuclear energies. Sodium oxalate is used as an antienzyme to retard tooth decay. In the drug industry sodium is used to compound with pharmaceuticals to make them water-soluble salts. Sodium is a plentiful element, easily available, and is one of the most widely used.

Sodium carbonate is best known under the name soda ash because sodium carbonate occurs in (and once was extracted from) plant ashes. Most sodium carbonate is produced by the Solvay or ammonia-soda process. In an initial reaction, salt is converted to sodium carbonate, which precipitates and is then separated.

Some soda ash is made synthetically by the Solvay process although an increasing amount is obtained from lake brines. Commercial grades of soda ash are available as 48% (Na_2O) light and dense and has 58% (Na_2O) light and dense; light and dense refers to apparent bulk density. Ordinarily 48%–58% grades are available in either light or dense but contain NaCl , which may affect certain ceramic uses. A 48% special grade is available in granular and extra light forms; it contains Na_2SO_4 . The material derived from natural sources is almost NaCl -free.

About one half of the total American soda ash production is used as a fluxing ingredient by the glass industry. The quality of soda ash in glass batches varies with the type of glass being made.

Sodium sulfate, Na_2SO_4 , is also known in the anhydrous form as salt cake. The decahydrate, $\text{Na}_2\text{SO}_4 \cdot 10 \text{H}_2\text{O}$, is known as glauber salt.

Most sodium sulfate is produced synthetically as a byproduct or coproduct in various industries.

Sodium aluminate, $\text{Na}_2\text{OAl}_2\text{O}_3$, whose melting point is 1650°C , is soluble in water and sodium carbonate. Sodium aluminate has found use as a setting up agent for acid-resistant enamel. It is prepared by heating together bauxite and slips. When used in this capacity, it affords easier control of the slip than can be obtained by the use of alum or sulfuric acid, because of its tendency to stabilize the mobility and yield values. Sodium aluminate is also used as a substitute for sodium silicate and sodium carbonate and pottery slips.

Sodium antimonate (sodium meta-antimonate), $\text{Na}_2\text{OSb}_2\text{O}_5 \cdot 5\text{H}_2\text{O}$, is a white powder insoluble in water and fruit acids. Sodium antimonate is extremely stable at high temperatures and does not decompose below 1427°C . It is usually made from antimony oxide, caustic soda, and sodium nitrate. Sodium antimonate is used as the principal opacifier in dry-process enamel frits for cast iron sanitary-ware and in some of the acid-resistant enamel frits for sheet steel. It is used in cast iron enamels; sodium antimonate is generally recognized as being more desirable than antimony trioxide.

Sodium cyanide is a salt of hydrocyanic acid of the composition NaCN , used for carburizing steel for case hardening, for heat-treating baths, for electroplating, and for the extraction of gold and silver from their ores. For carburizing steel it is preferred to potassium cyanide because of its lower cost than its higher content of available carbon. It contains 53% CN, as compared with 40% of potassium cyanide. The nitrogen also aids in forming the hard case on the steel. The 30% grade of sodium cyanide, melting at 679°C , is used for heat-treating baths instead of lead, but it forms a slight case on the steel. Sodium cyanide is very unstable, and on exposure to moist air liberates the highly poisonous hydrocyanic acid gas, HCN . For gold and silver extraction it easily combines with the metals, forming soluble double salts, $\text{NaAu}(\text{CN})_2$. Sodium cyanide is made by passing a stream of nitrogen gas over a hot mixture of sodium carbonate and carbon in the presence of a catalyst. It is a white crystalline powder, soluble in water. The white copper cyanide used in electroplating has the composition $\text{Cu}_2(\text{CN})_2$, containing 70% copper. It melts at 474.5°C and is insoluble in water, but is soluble in sodium cyanide solution. Sodium ferrocyanide, or yellow prussiate of soda, is a lemon-yellow crystalline solid, used for carburizing steel for case hardening. It is also employed in paints, in printing inks, and for the purification of organic acids; in minute quantities, it is used in salt to make it free-flowing. It is soluble in water. Calcium cyanide in powder or granulated forms is used as an insecticide. It liberates 25% of hydrocyanic acid gas.

Sodium nitrate (soda niter), NaNO_3 , with a melting point of 208°C , and decomposes at 380°C and is soluble. Sodium nitrate is used in enamel frits in quantities of 2%–8%. It is highly important that sufficient nitrate be present in enamels to prevent reduction of any easily reducible compounds in the batch, especially lead or antimony compounds. The function of sodium nitrate in glass is to oxidize organic matter that may contaminate batch materials, to prevent reduction of some of the batch constituents, to help maintain colors, and to speed the melt. It is the lowest melting of all glassmaking materials. Common applications of sodium nitrate are to ensure the pink color of manganese oxide and to prevent reductions of lead in potash lead glasses.

Sodium nitrite, NaNO_2 , is soluble in water. It is prepared from sodium nitrate by reduction with lead. Sodium nitrite has been used for some years as a mill addition, or as an addition after milling, to enamel ground coats to prevent rust while drying, and also as a setting-up agent. More recently, sodium nitrite has been used rather generally in cover coats to correct for tearing.

Sodium phosphate, has a melting point of 346°C and is soluble in water. Sodium phosphate has been recently added to glass batches, producing an opal glass of unusual properties. Three other forms

of the phosphate are available—monobasic, tribasic, and pyrophosphate. The last is most adaptable because it melts at 970°C in the anhydrous form. It is derived by the fusion of disodium phosphate.

Sodium silicate, is commonly made by melting sand and soda ash in a reverberatory furnace. Various proportions of the two ingredients are used and widely divergent characteristics result. The most alkaline liquid silicate made by this furnace process has a ratio of $1\text{Na}_2\text{O}:1.6\text{SiO}_2$ and the most siliceous liquid grade has a ratio of $1\text{Na}_2\text{O}:3.75\text{SiO}_2$.

Uses

The largest single use for sodium metal, accounting for about 60% of total production, is in the synthesis of tetraethyllead, and anti-knock agent for automotive gasolines.

A second major use is in the reduction of animal and vegetable oils to long-chain fatty alcohols; these alcohols are raw materials for detergent manufacture. This use has been decreasing in favor of production of such alcohols by high-pressure catalytic hydrogenation.

Sodium metal is also used in making sodium hydride, sodium amide, and sodium cyanide. It is also used in the synthesis of “isobasic acid.” The use of liquid sodium metal as a heat-transfer agent in nuclear reactors is also becoming increasingly important.

Sodium chloride is used in the manufacture of sodium hydroxide, sodium carbonate, sodium sulfate, and sodium metal. In sodium sulfate manufacture, hydrogen chloride is the coproduct; in metallic sodium manufacture, chlorine gas is the coproduct.

Rock salt is used in curing fish, in meat packing, in curing hides, and in making freezing mixtures. Food preparation, including canning and preserving, consumes much salt. Table salt accounts for only a small percentage of sodium chloride consumption, most of it going into the industrial uses outlined above.

Sodium hydroxide is perhaps the most important industrial alkali. Its major use is in the manufacture of chemicals, about 30% attributed to this category. The next major use is the manufacture of cellulose film and rayon, both of which proceed through soda cellulose (the reaction product of sodium hydroxide and cellulose); this accounts for about 25% of the total caustic soda production. Soap manufacture, petroleum refining, and pulp and paper manufacture each account for a little less than 10% of total sodium hydroxide use.

Sodium carbonate finds its major use in the glass industry, which takes about one third of total production. Approximately another third goes into the manufacture of soap, detergent, and various cleansers. The manufacture of paper and textiles, nonferrous metals, and petroleum products accounts for much of the balance.

The major consumer of sodium sulfate (salt cake) is the kraft paper industry. Increasing quantities of sodium sulfate are used in the manufacture of flat glass. Other uses of salt cake are in detergents, ceramics, mineral stock feeds, and pharmaceuticals.

In the area of biological activity, the sodium ion (Na^+) is the main positive ions present in extracellular fluids and is essential for maintenance of the osmotic pressure and of the water and electrolytic balances of body fluids.

Soft

The opposite of hard in its variations.

Softening

Various processes of reducing hardness and tensile strength and, usually increasing ductility, malleability and toughness. See *annealing*, *tempering*, and *normalizing*.

S

Softening Point

That temperature at which a glass fiber of uniform diameter elongates at a specific rate under its own weight when measured by standard ASTM test methods. The viscosity at the softening point depends on the density and surface tension. For example, for a glass of density 2.5 g/cm³ and surface tension 300 dynes/cm, the softening point temperature corresponds to a viscosity of 106.6 Pa s.

Softening Range

The range of temperatures within which a plastic changes from a rigid to a soft state. Actual values depend on the test method. Sometimes erroneously referred to as softening point.

Soft Magnetic Materials

Magnetic materials are broadly classified into two groups with either hard or soft magnetic characteristics. Hard magnetic materials are characterized by retaining a large amount of residual magnetism after exposure to a strong magnetic field. These materials typically have coercive force, H_c , values of several hundred to several thousand oersteds (Oe) and are considered to be permanent magnets. The coercive force is a measure of the magnetizing force required to reduce the magnetic induction to zero after the material has been magnetized. In contrast, soft magnetic materials become magnetized by relatively low strength magnetic fields, and when the applied field is removed, they return to a state of relatively low residual magnetism. Soft magnetic materials typically exhibit coercive force values of approximately 5 Oe to as low as 0.002 Oe. Soft magnetic behavior is essential in any application involving changing electromagnetic induction, such as solenoids, relays, motors, generators, transformers, magnetic shielding, and so on. Other important characteristics of magnetically soft materials include high permeability, high saturation induction, low hysteresis-energy loss, low eddy-current loss in alternating flux applications, and in specialized cases, constant permeability at low field strengths and/or a minimum or definite change in permeability with temperature.

Cost, availability, strength, corrosion resistance, and ease of processing are among the key factors that influence the final selection of a soft magnetic material. Magnetically soft materials manufactured in large quantities include high-purity irons, low-carbon ($\leq 0.08\%$ C) steels that contain additions of phosphorus (0.03%–0.15%) and manganese (0.25%–0.75%) to increase the electrical resistivity, silicon (electrical) steels containing 2%–3.5% Si, iron-nickel alloys with nickel contents ranging from 45% to 79%, iron-cobalt alloys (for example, 49Fe–49Co–2V and Fe–27Co–0.6Cr), ferritic stainless steels, and ferrites (manganese–zinc and nickel–zinc in particular). Soft magnetic amorphous materials are also being produced. See *metallic glass*.

Soft Solder

Alloys primarily of lead and tin. They meld at low temperatures to provide a fairly strong joint and seal between metals such as lead, steel (usually pre-tinned), copper or copper alloys. The term soft solder is in contradiction to hard solder, the latter term being applied to braze filler metals and silver solders which, apart from higher strength and hardness, have melting range commencing above 450°C, the usually accepted differentiation between solder and brazing temperatures. The soft solders offer a variety of compositions with a useful variation in freezing ranges. Plumbers solder,

70% lead, 30% tin, has a wide freezing range, 250°C–183°C, with a long pasty stage allowing the joint to be “wiped” to a smooth profile. Electricians solder, also termed Tinmans Solder is of approximately eutectic composition, 62% tin, 38% lead, freezing at 183°C. The soldering processes and techniques are largely similar to brazing apart from the lower temperatures and lower strength. However, because of the lower temperature, small solder joints can be made with the hard tip or “bit” of a soldering iron. Another common process is wave soldering in which the components to be soldered, for example, circuit boards, are suspended joint face down, just above a bath of solder. A wave is then introduced in the surface of the bath and the component passed over skimming the wave. In most cases a flux is applied prior to, or during, soldering to clean the surfaces of oxide and other contaminants which would inhibit wetting and bonding. See preferred term *solder*.

Soft Soldering

See preferred term *soldering*.

Soft Temper

Same as *dead soft temper*.

Soft Water

Water that is free of magnesium or calcium salts.

Soil

Undesirable material on a surface that is not an integral part of the surface. Oil, grease, and dirt can be soils; a decarburized skin and excess *hard chromium* are not soils. Loose scale is soil; hard scale may be an integral part of the surface and, hence, not soil.

Sol

A colloidal suspension comprised of discrete or separate solid particles suspended in a liquid. Differs from a solution, though one merges into the other. Compare with *gel*.

Solder Alloys

These are alloys of two or more metals used for joining other metals together by surface adhesion without melting the base metals as in welding and without requiring as high a temperature as in brazing. However, there is often no definite temperature line between soldering alloys and brazing filler metals. A requirement for a true solder is that it have a lower melting point than the metals being joined and an affinity for, or be capable of uniting with, the metals to be joined.

Types and Forms

The most common solder is called half-and-half, plumbers' solder, or ASTM solder class 50A, and is composed of equal parts of lead and tin. It melts at 183°C. The density of the solder is 8802 kg/m³, the tensile strength is 39 MPa, and the electrical conductivity is 11% that of copper. SAE (Society of Automotive Engineers) solder No.1 has 49.5%–50.0% tin, 50% lead, 0.12% max antimony, and 0.08% max copper. It melts at 181°C. Much commercial half-and-half, however, usually contains larger proportions of lead and some antimony, with

less tin. These mixtures have higher melting points, and solders with less than 50% tin have a wide melting range and do not solidify quickly. Sometimes a wide melting range is desired, in which case a wiping solder with 38%–45% of tin is used. A narrow-melting range solder, melting at 183°C–185°C, ASTM solder class 60A, contains 60% tin and 40% lead. A 42% tin and 58% lead solder has a melting range of 183°C–231°C. Slicker solder is the best quality of plumbers' solder, containing 63%–66% tin and the balance lead.

Solder alloys are available in a wide range of sizes and shapes, enabling users to select that one that best suits their application. Among these shapes are pig, slab, cake or ingot, bar, paste, ribbon or tape, segment or drop, powder, foil, sheet, solid wire, flux cored wire, and preforms. There are 11 major groups of solder alloys:

Tin-Antimony

Useful at moderately elevated operating temperatures, around 149°C, these solders have higher electrical conductivity than the tin-lead solders. They are recommended for use where lead contamination must be avoided. A 95% Sn–5% Sb alloy has a solidus of 235°C, a liquidus of 240°C, and a resulting pasty range of –11.1°C.

Tin-Lead

Constituting the largest group of all solders in use today, the tin-lead solders are used for joining a large variety of metals. Most are not satisfactory for use above 149°C under sustained load.

Tin-Antimony-Lead

These may normally be used for the same applications as tin-lead alloys with the following exceptions: aluminum, zinc, or galvanized iron. In the presence of zinc the solders form a brittle intermetallic compound of zinc and antimony.

Tin-Silver

These have advantages and limitations similar to those of tin-antimony solders. The tin silvers, however, are easier to apply with a rosin flux. Relatively high cost confines these solders to fine instrument work. Two standard compositions; 96.5% Sn–3.5% Ag, the eutectic; 95% Sn–5% Ag, with a solidus of 221°C and liquidus of 245°C.

Tin-Zinc

These are principally for soldering of aluminum since they tend to minimize galvanic corrosion.

Lead-Silver

Tensile, creep, and shear strengths of the solders are usually satisfactory up to 177°C. Flow characteristics are rather poor and these solders are susceptible to humid atmospheric corrosion in storage. The use of a zinc chloride-base flux is recommended to produce a good joint on metals uncoated with solder.

Cadmium-Silver

The primary use of cadmium-silver solder is in applications where surface temperature will be higher than permissible with lower melting solder. Improper use may lead to health hazards. The solder has a composition of 95% Cd–5% Ag. Solidus is 338°C and liquidus is 393°C.

Indium-Lead Alloys

These are alkali-resistant solders. A solder with 50% lead and 50% indium melts at 182°C, and is very resistant to alkalies, but lead-tin solders with as little as 25% indium are resistant to alkaline

solutions, have better wetting characteristics, and are strong. Indium solders are expensive. Adding 0.85% silver to a 40% tin soft solder gives equivalent wetting on copper alloys to a 63% tin solder, but the addition is not effective on low-tin solders. A gold-copper solder used for making high-vacuum seals and for brazing difficult metals such as iron-cobalt alloys contain 37.5% gold and 62.5% copper.

Palladium-Nickel

A palladium-nickel alloy with 40% nickel has a melting point about 1237°C. The brazing filler metals containing palladium are useful for a wide range of metals and metal to ceramic joints.

The remaining four groups of Zn–Al, Cd–Zn, and solders containing bismuth and indium were covered earlier.

Silver Solder

Silver solder is high-melting-point solder employed for soldering joints where more than ordinary strength and, sometimes, electric conductivity are required. Most silver solders are copper-zinc brazing filler metals with the addition of silver. They may contain 9% to 80% silver, and the color varies from brass yellow to silver white. Cadmium may also be added to lower the melting point. Silver solders do not necessarily contain zinc, and brazing filler metals of silver and copper in proportions are arranged to obtain the desired melting point and strength. A silver braze filler metal with a relatively low melting point contains 65% silver, 20% copper, and 15% zinc. It melts at 693°C, has a tensile strength of 447 MPa, and elongation 34%. The electrical conductivity is 21% that of pure copper. A solder melting at 760°C contains 20% silver, 45% copper, and 35% zinc. ASTM silver solder No. 3 is this solder with 5% cadmium replacing an equal amount of the zinc. It is general-purpose solder. ASTM silver solder No. 5 contains 50% silver, 34% copper, and 16% zinc. It melts at 693°C, and is used for soldering electrical work and refrigeration equipment.

Any tin present in silver solders makes them brittle; lead and iron make the solders difficult to work. Silver solders are malleable and ductile and have high strength. They are also corrosion resistant and are especially valuable for use in food machinery and apparatus where lead is objectionable. Small additions of lithium to silver solders increase fluidity and wetting properties, especially for brazing stainless steels or titanium. Sil-Fos is a phosphor-silver brazing solder with a melting point of 704°C. It contains 15% silver, 80% copper, and 5% phosphorus. Lap joints brazed with Sil-Fos have a tensile strength of 206 MPa. The phosphorus in the alloy acts as a deoxidizer, and the solder requires little or no flux. It is used for brazing brass, bronze, and nickel alloys.

Another grade, Easy solder, contains 65% silver, melts at 718°C, and is a color match for sterling silver. TL silver solder has only 9% silver and melts at 871°C. It is brass yellow in color, and is used for brazing nonferrous metals. Sterling silver solder, for brazing sterling silver, contains 92.8% silver, 7% copper, and 0.2% lithium. Flow temperature is 899°C.

A lead-silver solder to replace tin solder contains 96% lead, 3% silver, and 1% indium. It melts at 310°C, spreads better than ordinary lead-silver solders, and gives a joint strength of 34 MPa. Silver-palladium alloys for high-temperature brazing contains from 5% to 30% palladium. With 30%, the melting point is about 1232°C. These alloys have exceptional melting and flow qualities and are used in electronic and spacecraft applications.

Cold Solders

Cold solder, use for filling cracks in metals, may be a mixture of a metal powder in a pyroxylin cement with or without a mineral filler,

S

but the strong cold solders are made with synthetic resins, usually epoxies, cured with catalysts, and with no solvents to cause shrinkage. The metal content may be as high as 80%. Devcon F, for repairing holes in castings, has 80% aluminum powder and 20% epoxy resin. It is heat-cured at 66°C, giving high adhesion. Epoxyn solder is aluminum powder in an epoxy resin in the form of a putty for filling cracks or holes in sheet metal. It cures with a catalyst. The metal-epoxy mixtures give a shrinkage of less than 0.2%, and they can be machined and polished smooth.

Lead-Free Solder Replacements

In spite of the sustained efforts of researchers and technology leaders in packaging, to date there is no lead-free solder alloy that is a drop-in replacement for tin-lead solder in assembly processes. Because tin-lead solder has been used for so long and is so much a part of the typical process engineer's thinking, the quest for an affordable lead-free alloy replacement is facing mounting pessimism that the effort will be successful.

On the other hand, optimism that adhesive-type solders will prove to be a serious alternative to metallurgical materials continues to grow. These polymer-based conductive adhesives are being used in various applications previously "reserved" for tin-lead solders. Regular production equipment and traditional assembly processes are producing high-quality assemblies with demonstrated long-term reliability using the new solders. And for some products, polymers are considered an enabling technology. One major market is the polyester-based flexible circuit market, particularly those built using polymer thick film.

Polymer Solders

Polymer solders are also known as "conductive adhesives," or materials that provide the dual functions of electrical connection and mechanical bond. The adhesive components of a typical material are some form of polymer, i.e., long-chain molecules widely used to produce structural products, which are also known for their excellent dielectric properties. Already used extensively as electrical insulators, as solders their necessary conductivity is accomplished by adding highly conductive fillers to the polymer binders.

The most common polymer solders are silver-filled thermosetting epoxies supplied as one-part thixotropic pastes. Silver is used not only because it is usually cost-effective, but also for its unique conductive oxide. A blend of silver powder and flakes achieves high conductivity while maintaining good printability. Because the mechanical strength of the joint is provided by the polymer, the challenge in a formulation is to use the maximum metal loading without sacrificing the required strength. (Some polymer solders contain more than 80% metal filler by weight.)

Polymer solders do not typically form metallurgical interfaces in the usual sense. Electrical integrity requires that the metal filler particles be in close contact to form a conductive path between the circuit trace and the component lead. Ideally, the silver flakes will overlap and smaller particles will fill in the gaps to form a conductive chain.

In the past, polymer solders were successful only on circuits using precious-metal conductors. This was because junction resistance was seen to increase to unacceptable levels when ordinary printed circuit boards and components were joined with these materials. To solve the instability problem it was necessary to create stable, non-metallurgical junctions with oxidizable surfaces. For example, one polymer-solder formulation, used on flexible circuits and recently

optimized for rigid boards, provides junction stability between solder-coated and bare-copper surfaces via polymer shrinkage during curing to force irregular particles through the interface oxides.

Advantages in using polymer solders include compatibility with the range of surfaces including some nonsolderable substrates; low-temperature processing, resulting in lower thermal stress; no pre- or postclean requirements, thereby reducing equipment needs and cycle times, and lowering or eliminating the release of volatile organic compounds.

Solderability

The relative ease and speed with which a surface is wetted by molten solder.

Solder Embrittlement

Reduction in mechanical properties of a metal as a result of local penetration of solder along grain boundaries.

Solder Lock

The phenomenon whereby if a soft soldered joint between copper components is heated for too long a period, including remelting, the copper and solder mutually diffuse causing the melting point of the solder to increase to such an extent that it cannot be melted by the usual heating system. Plumbers sometimes use the term "Seized Joint" for the phenomenon.

Solder Materials

Fluxes

Fluxes range from very mild substances to those of extreme chemical activity. For centuries, rosin, a pine product, has been known as an effective and practically harmless flux. It is used widely for electrical connections in which utmost reliability, freedom from corrosion, and absence of electrical leakage are essential. When less stringent requirements exist and when less carefully prepared surfaces are to be soldered, rosin is mixed with chemically active agents that aid materially in soldering.

The rosin-type fluxes may be incorporated as the core of wire solders or dissolved in various solvents for direct application to joints prior to soldering.

Inorganic salts are widely used where stronger fluxes are needed. Zinc chloride and ammonium chloride, separately or in combination, are most common. They may also be obtained as so-called acid-core solder wire or in petroleum jelly as paste flux. All of the salt-type fluxes leave residues after soldering that may be a corrosion hazard. Washing with ample water accomplished by brushing is generally wise.

Solder Paint

A suspension of powdered soft solder and flux which can be painted onto the surface to be soldered. After heating to fuse the solder and form the joint the flux is cleaned off.

Soldering

A group of processes that join metals by heating them to a suitable temperature below the solidus of the base metals and applying

a filler metal having a liquidus not exceeding 450°C. Molten filler metal is distributed between the closely fitted surfaces of the joint by capillary action. See also *solder*.

Soldering Flux

See *flux* (2).

Soldering Gun

An electrical soldering iron with a pistol grip and a quick heating, relatively small bit.

Soldering Iron

A soldering tool having an internally or externally heated metal bit usually made of copper.

Solder Short

See *bridging* (5).

Sol–Gel Process

This is a chemical synthesis technique for preparing gels, and glasses, and ceramic powders. The synthesis of materials by the sol–gel process generally involves the use of metal alkoxides, which undergo hydrolysis and condensation polymerization reactions to yield gels.

The production of glasses by the sol–gel method is an area that has important scientific and technological implications. For example, the sol–gel approach permits preparation of glasses at far lower temperatures than is possible by using conventional melting. It also makes possible synthesis of compositions that are difficult to obtain by conventional means because of problems associated with volatile authorization, high melting temperatures, or crystallization. In addition, the sol–gel approach is a high-purity process that leads to excellent homogeneity. Finally, the sol–gel approach is adaptable to producing films and fibers as well as bulk pieces, that is, monoliths (solid materials are macroscopic dimensions, at least a few millimeters on a side).

Glass Formation

Formation of silica-based materials is the most widely studied system. However, an anonymous range of multicomponent silicate glass compositions have also been prepared.

The sol–gel process can ordinarily be divided into the following steps: forming a solution, adulation, drying, and densification.

Hydrolysis and Condensation

In general, the processes of hydrolysis and condensation polymerization are difficult to separate. The hydrolysis of the alkoxide need not be complete before condensation starts; and in partially condensed silicate, hydrolysis can still occur at unhydrolyzed sites. Several parameters have been shown to influence the hydrolysis and condensation polymerization reactions: these include the temperature, solution pH, the particular alkoxide precursor, the solvent, and the relative concentration of each constituent. In addition, acids and bases catalyze the hydrolysis and condensation polymerization reactions; therefore, they are added to help control the rate and the extent of these reactions.

Microstructural Development

The conditions under which hydrolysis and condensation occur have a profound effect on gel growth and morphology. These structural conditions greatly influence the processing of sol–gel glasses into various forms. It is well established, for example, that acid-catalyzed solutions with low water content (that is conditions that produce linear polymers) offer the best type of solution for producing fibers.

Gelation and Aging

As the hydrolysis and condensation polymerization reactions continue, viscosity increases until the solution ceases to flow. The time required for gelation to occur is an important characteristic that is sensitive to the chemistry of the solution and the nature of the polymeric species. This sol-to-gel transition is irreversible, and there is little if any change in volume.

Drying

The drying process involves the removal of the liquid phase; the gel transforms from an alcogel to a xerogel. Low-temperature evaporation is frequently employed, and there is considerable weight loss and shrinkage. The drying stage is a critical part of the sol–gel process. As evaporation occurs, drying stresses arise that can cause catastrophic cracking of bulk materials.

Densification

The final stage of the sol–gel process is densification. At this point the gel-to-glass conversion occurs and the gel achieves the properties of the glass. As the temperature increases, several processes occur, including elimination of residual water and organic substances, relaxation of the gel structure, and, ultimately, densification.

Applications

The sol–gel process offers advantages for a broad spectrum of materials applications. The types of materials go well beyond silica and include inorganic compositions that possess specific properties such as ferroelectricity, electrochromism, or superconductivity. The most successful applications utilize the composition control, microstructure control, purity, and uniformity of the method combined with the ability to form various shapes at low temperatures. Films and coatings were the first commercial applications of the sol–gel process. The development of the sol–gel-based optical materials has also been quite successful, and applications include monoliths (lenses, prisms, lasers), fibers (waveguides), and a wide variety of optical films. Other important applications of sol–gel technology utilize controlled porosity and high surface area for catalyst supports, porous membranes, and thermal insulation.

Solid Cutters

Cutters made of a single piece of material rather than a composite of two or more materials.

Solid Density

See *density, absolute*.

S

Solid-Film Lubrication

Lubrication by application of a *solid lubricant*.

Solidification

The process whereby a metal changes, on cooling, from the fully liquid state to the fully solid-state. Solidification commences when a small group of atoms forms a nucleus from which a crystal (grain) grows by additional atoms attaching themselves at specific locations to build up the crystal lattice. Each crystal develops by forming, in three dimensions, a system of angular branches termed a dendrite. As a dendrite grows the gaps between main branches are filled by further branches. Eventually, in most practical cases, the dendrite will meet a neighboring dendrite growing to form another crystal. The line at which they meet is termed the crystal—or grain boundary. Provided sufficient molten metal is available in the immediate vicinity will be filled with solid material. If not, porosity will remain. This is termed *interdendritic porosity* when located within a grain at gaps in the dendritic branches or *inter-crystalline* or *intergranular porosity* if it is located at the grain boundaries. All pure metals solidify at a fixed temperature while alloys, except in special cases, solidify progressively over a temperature range. If an alloy is held at a temperature within the range it will comprise a pasty mixture, sometimes described as a *mush* or *slush*, of solid and liquid components in fixed proportions at specific compositions defined by the bulk alloy composition and the temperature. See also *segregation* and *lever rule*.

Solidification Cracking

Cracking occurring during solidification, usually as a result of stress and imposed by constraint of thermal contraction. Such cracking is normally located at grain boundaries as these are the last material to solidify and hence are relatively weak and unable to withstand the loads imposed by the surrounding material as it cools.

Solidification Range

The temperature between the liquidus and the solidus.

Solidification shrinkage

The reduction in volume of metal from beginning to end of solidification. See also *casting shrinkage*.

Solidification Shrinkage Crack

A crack that forms, usually at elevated temperature, because of the internal (shrinkage) stresses that develop during solidification of a metal casting. Also termed hot crack.

Solid Lubricant

Any solid used as a powder or thin film on a surface to provide protection from damage during relative movement and to reduce friction and wear. Examples include molybdenum disulfide, graphite, polytetrafluoroethylene (PTFE), and mica.

Solid-Metal Embrittlement

The occurrence of *embrittlement* in a material below the melting point of the embrittled link species. See also *liquid-metal embrittlement*.

Solid Particle Erosion

Erosion by solid particles entrained in a fluid. The term is usually used in the context of damage observed in the early stages of blades in a steam turbine. Such damage is caused by particles of oxide or other debris entrained in the steam from earlier parts of the system. Oxides may be released by spalling in the super heater and reheater stages and debris may be produced by poor practice during welding. This contrasts with the more common erosion observed in the final stages of blades that are exposed to steam cooled to a stage where large quantities of water droplets are produced. See *steam erosion*.

Solid-Phase Chemical Dosimeter

An apparatus that measures radioactivity by using plastic, dyed plastic, or glass with an optical density, usually in the visible range, that changes when exposed to ionizing radiation. Examples currently in use include dyed polymethyl methacrylate (red perspex), undyed polyvinyl chloride, dyed polyamide (blue dye in a nylon matrix), and dyed polychlorostyrene (green dye in a chlorostyrene matrix). Solid-phase chemical dosimetry is generally considered to be a secondary-standard dosimetry system.

Solid-Phase Diffusion Welding

See *diffusion welding*.

Solid-Phase Forming

The use of metalworking techniques to form thermoplastics in a solid phase. Procedure begins with a plastic blank that is heated and fabricated (that is, forged) by bulk deformation of the materials in constraining dies by the application of force. Also called solid-state stamping.

Solid Shrinkage

See *casting shrinkage*.

Solid Solubility

See *solution* and *phase*.

Solid Solution

A single, solid, homogeneous crystalline phase containing two or more chemical species. See *solution* and *phase*.

Solid Solution Hardening/Strengthening

See *solution hardening*.

Solid State

(1) Pertaining to circuits and components using semiconductors as substrates. (2) In the context of electronics this term implies electronic devices that comprise only solid materials such as transistors rather than devices containing gases such as thermionic valves.

Solids Content

The percentage by weight of the nonvolatile matter in an adhesive. The actual percentage of the nonvolatile matter in an adhesive will

vary according to the analytical procedure that is used. A standard test method must be used to obtain consistent results.

Solid-State Sintering

A sintering procedure for compacts or loose powder aggregates during which no component melts. Contrast with *liquid phase sintering*.

Solid-State Welding

A group of welding processes that join metals at temperatures essentially below the melting points of the base materials, without the addition of a brazing or soldering filler metal. Pressure may or may not be applied to the joint. Welding that does not involve melting of either the parent materials or a filler. Examples include *cold welding*, *diffusion welding*, *forge welding*, *hot pressure welding*, and *roll welding*.

Solidus

(1) The highest temperature at which a metal or alloy is completely solid. (2) In a *phase diagram*, the locus of points representing the temperatures at which the various compositions stop freezing upon cooling or begin to melt upon heating. (3) The line defining the lower limit of the melting range of an alloy. A pure metal melts and solidifies at a specific temperature but, apart from special cases, alloys melt and solidify progressively over a range of temperature. Within the range the alloy will exist as a pasty mixture of solid plus liquid. When represented graphically the line defining the upper limit of the range is referred to as the *liquidus* and that defining the lower limit is the *solidus*. See also *liquidus*.

Soluble Anode Process

Various processes of refining metals by making the impure material the anode of a solute. The material taken into solution by the solvent.

Soluble Oil

A mineral oil containing additives that enable it to form a stable emulsion with water. Soluble oils are used as cutting or grinding fluids.

Solute

The component of either a liquid or solid solution that is present to a lesser or minor extent; the component that is dissolved in the solvent.

Solution

(1) In chemistry, a homogeneous dispersion of two or more types of molecular or ionic species. Solutions may be composed of any combination of liquids, solids, or gases, but they always consist of a single phase. (2) A phase containing more than one component. It is commonly recognized that a liquid can form a solution, i.e., water can dissolve salt to form a salt solution. Similarly, metals and the solid-state can form solutions. As with liquids the principal constituent will be termed the *solvent* and the secondary consistor is the *solute*. When the solvent contains the maximum possible amount to solute it is termed *saturated*. Extreme treatment, which precludes equilibrium, for example, fast cooling, can cause excess quantities of solute to be retained in the solvent. Such unstable solutions are

termed *supersaturated*. A solid solution, in equilibrium, will have a uniform composition at all positions and, under the microscope will appear as a featureless single phase. In the cases of some pairs of metals, such as copper and nickel, the two are completely soluble in each other at all compositions but in most alloy systems solubility is limited and multiple phases occur. Where the composition range of a phase includes the pure metal it is termed a primary solid solution, otherwise it is termed a secondary solid solution or intermediate phase. Where the range of the intermediate phase is narrow and based on a simple ratio of the atoms of the two elements it may be termed an *intermetallic compound*. In a substitutional solid solution the solute atoms take positions on the crystal lattice normally occupied by a solvent atom. In an interstitial solid solution the relatively small solute atoms fit into the spaces between solvent metal atoms.

Solution Anneal

A heat treatment intended to affect annealing, i.e., softening and recrystallization of work hardened material, and to take into solution all (or most) precipitates. It is also implied that there will be no significant reprecipitation during subsequent cooling. The term is often used in the context of austenitic stainless steels and where such material is intended for high temperature service there may also be an application that's of grain growth is intended to enhance creep properties.

Solution Hardening

Hardening of an alloy as a result of one or more elements being in solid solution in another. The effect results from the different size of the solute atoms distorting the crystal lattice of the solvent and thereby impeding dislocation movement. The term is sometimes used casually to refer to the hardening process involving solution treatment plus precipitation hardening but this is usually regarded as erroneous.

Solution Heat Treatment

Heating an alloy to a suitable temperature, holding at that temperature long enough to cause one or more constituents to enter into *solid solution*, and then cooling rapidly enough to hold those constituents in solution.

Solution Potential

Electrode potential where half-cell reaction involves only the metal electrode and its ion.

Solvation

The process of swelling, gelling, or dissolving a resin by a solvent or *plasticizer*.

Solvay Process

A method for producing *soda ash* that involves the reaction of salt (NaCl) and limestone to form sodium carbonate (Na_2CO_3) with calcium chloride (CaCl_2) as a by-product.

Solvent

A material, usually a liquid, having the power of dissolving another material and forming a homogeneous mixture called a **solution**.

S

The mixture is physical, and no chemical action takes place. A solid solution is such a mixture of two metals, but the actual mixing occurs during the liquid or gaseous state. Some materials are soluble in certain other materials in all proportions, while others are soluble only up to a definite percentage and the residue is precipitated out of solution. Homogeneous mixtures of gases may technically be called solutions, but are generally referred to only as mixtures.

The usual industrial application of solvents are for putting solid materials into liquid solution for more convenient chemical processing, for thinning paints and coatings, and for dissolving away foreign matter as in dry-cleaning textiles. But they may have other uses, such as absorbing dust on roadways and killing weeds. They have an important use in separating materials, for example, in the extraction of oils from seeds. In such use a **clathrate** is a solid compound added to the solution containing a difficult-to-extract material, but which is trapped selectively by the clathrate. The solid clathrate is then filtered out and processed by heat or chemicals to separate the desired compound. **Antifoamers** are chemicals, such as the silicones, added to solvents to reduce foam so that processing equipment can be used to capacity without spillover.

The usual commercial solvents for organic substances are the alcohols, ether, benzene, and turpentine, the latter two being common solvents for paints and varnishes containing gums and resins. The so-called **coal-tar solvents** are light oils from coal tar. **Solvent oils**, from coal tar, are Amber to dark liquids with distillation ranges from about 150°C to 340°C, with specific gravity is 0.910–0.980. They are used as solvents for asphalt varnishes and bituminous paints. **Shingle stains** are amber to dark grades of solvent oils of specific gravity 0.910–0.930.

A valuable solvent for rubbers and many other products is **carbon bisulfide**, CS₂, also called, **carbon disulfide**, made by heating together carbon and sulfur. It is flammable and toxic. When pure, it is nearly odorless. **Ethyl acetate**, made from ethyl alcohol and acetic acid, is an important solvent for nitrocellulose and lacquers. It is liquid, boiling at 77°C. One of the best solvents for cellulose is **cuprammonium hydroxide**. Amyl and other alcohols, amyl acetate, and other volatile liquids are used for quick-drying lacquers, but many synthetic chemicals are available for such use. **Dioxan**, a water-white liquid is a good solvent for cellulose compounds, resins, and varnishes, and is used also in **paint removers**, which owe their action to their solvent power.

The chlorinated hydrocarbons have powerful solvent action on fats, waxes, and oils and are used in degreasing. Of major commercial significance are **perchloroethylene (PCE)**, **trichloroethylene (TCE)**, and **1,1,1-trichloroethane (1,1,1-TCA)**. The biggest industrial use of PCE, also known as **tetrachloroethylene** and **Perc**, is as a dry-cleaning solvent because of its nonflammability, and high solvency, vapor pressure, and stability. The largest applications of TCE and 1,1,1-TCA have been in metal cleaning, which also consumes significant quantities of PCE. Because 1,1,1-TCA has been implicated in ozone depletion of the stratosphere, its use is being discontinued. Hydrofluoroether-based solvents have similar boiling points to 1,1,1-TCA and CFC-113 and are possible alternatives to 1,1,1-TCA.

Dichloromethane, known also as **methylene chloride** and **carrene**, is a colorless, nonflammable liquid. It is soluble in alcohol and is used in paint removers, as a dewaxing solvents for oils, for degreasing textiles, and as a refrigerant. **Cyclohexane**, made by the hydrogenation of benzene, is a good solvent for rubbers, resins, fats, and waxes.

A **plasticizer** is a liquid or solid that dissolves in or is compatible with a resin, gum, or other material and renders it plastic, flexible or easy to work. A sufficient quantity of plasticizer will result in a viscous mixture which consists of a suspension of solid grains of the

resin or gum in the liquid plasticizer. The plasticizer is in that sense a solvent, but unlike an ordinary solvent the plasticizer remains with the cured resin to give added properties to the materials, such as flexibility.

Solvent-Activated Adhesive

A dry-film adhesive that is rendered tacky by the application of a solvent just prior to use.

Solvent Adhesive

An adhesive having a volatile organic liquid as a vehicle. This term excludes water-base adhesives.

Solvent Molding

Process for forming thermoplastic articles by dipping a male mold in a solution or by dispersing the resin and drawing off the solvent, leaving a layer of plastic film adhering to the mold.

Solvus

In a phase or equilibrium diagram, the locus of points representing the temperature at which solid phases with various compositions coexist with other solid phases, that is, the limits of solid solubility.

Sommerfeld Number

A dimensionless number that is used to evaluate the performance of Journal bearings. It is numerically defined as follows:

$$\frac{P}{\eta U} \left(\frac{c}{r} \right)^2$$

where

P is the load per unit width

η is the dynamic viscosity

U is the surface velocity

c is the radial clearance

r is the bearing radius

At lower concentricities it is convenient to use the Sommerfeld number and the form given. Because it tends to infinity as the eccentricity approaches unity, the reciprocal form is frequently used in the case of heavily loaded bearings. The expression:

$$\frac{\eta N}{p} \left(\frac{r}{c} \right)^2$$

in which

N is the frequency of rotation

p is the pressure, is sometimes referred to as the Sommerfeld number, particularly in the United States

See also *Ocvirk number*.

Sonic Fatigue

Same as *acoustic fatigue*.

Sonic Testing

Any inspection method that uses sound waves (in the audible frequency range, about 20–20,000 Hz) to induce a response from a part or test specimen. Sometimes, but inadvisably, used as a synonym for *ultrasonic testing*. Usually, testing merely involves striking the component in question and listening to the “ring” emitted. A long pure tone implies freedom from gross cracks while a brief dull note indicates cracking. See also *ultrasonic testing*.

Sonotrode

The vibration emitting head of an ultrasonic welding unit.

Sound and Vibration Insulators

Materials used for reducing the transmission of noise. Insulators are used to impede the passage of sound waves, as distinct from isolators used under machines to absorb the vibrations that cause the sound. For factory use the walls, partitions, and ceilings offer the only media for the installation of sound insulators. All material substances offer resistance to the passage of sound waves, and even glass windows may be considered as insulators. But the term refers to the special materials placed in the walls for the specific purpose. Insulators may consist of mineral wool, hair felt, foamed plastics, fiber sheathing boards, or simple sheathing papers. Sound insulators are marketed under a variety of trade names, such as **Celotex**, made from the bagasse, and **Fibrofelt**, made from flax or rye fiber. Wheat straw is also used for making insulating board. Sound insulators are often also heat insulators. **Linofelt** is a sound- and heat-insulating material used for walls. It consists of a quilt of flax fiber between tough waterproof paper. It comes in sheets. **Fiber metal**, of Technetics Corp., comprises randomly interlocked similar metal fibers, with the fibers bonded by sintering at all contact points. Similar to nonwoven textile felts, its trade name is **Feltmetal**, and it is available in sheet form in various fibers, thickness, and porosity. 316 and 347 stainless steel and aluminum-alloy fibers are used mainly for noise reduction of aircraft turbines, turbine blowers, and high-speed fans. Noise reduction is by *resistive absorption*, by which the amplitude of sound waves is reduced by converting most of the acoustic energy into heat. Other applications include abrasable seals, using Hastelloy X fibers, and high-temperature thermal insulation, using an iron, chromium, aluminum, and yttrium alloy.

Vibration insulators, or **isolators**, to reduce vibrations that produce noises, are usually felt or fiberboards placed between the machine base and the foundation, but for heavy pressures they may be metal wire helically wound or specially woven, deriving their effectiveness from the form rather than the material.

Source (x-Rays)

The area emitting primary x-rays in a diffraction experiment. The actual source is always the focal spot of the x-ray tube, but the virtual source may be a slit or pinhole, depending on the conditions of the experiment.

Sour Gas

A gaseous environment containing hydrogen sulfide and carbon dioxide in hydrocarbon reservoirs. Prolonged exposure to sour gas can lead to *hydrogen damage*, *sulfide-stress cracking*, and/or *stress-corrosion cracking* in ferrous alloys.

Sour Water

Waste waters containing fetid materials, usually sulfur compounds.

Sow Block

A block of heat-treated steel place between the anvil of the hammer and the forging die to prevent undue wear to the anvil. Sow blocks are occasionally used to hold insert dies. Also called anvil cap. See also the terms *drop hammer* and *gravity hammer*.

Soybean Oil

Biodiesel fuel, a combination of natural oil or fat with an alcohol such as methanol or ethanol, could help the U.S. reduce air pollution and its dependence on imported oil.

Soybean oil is the most commonly used feedstock in the U.S. Biodiesel works in all conventional diesel engines and can be distributed through the existing industry infrastructure.

Using 100% biodiesel fuel reduces carbon dioxide emissions by more than 75% compared to petroleum diesel. Using a blend of 20% biodiesel reduces them by 15%. The fuel also produces less particulate, carbon monoxide, and sulfur emissions, all targeted as public health risks. On the downside, biodiesel is more expensive than petroleum diesel and it produces slightly higher amounts of nitrogen oxide, a pollutant.

Space-Charge Aberration

In electron microscope, an aberration resulting from the mutual repulsion of the electrons in a beam. This aberration is most noticeable in low-voltage, high-current beams. This repulsion acts as a negative lens, causing rays, which were originally parallel, to diverge. See also *aberration*.

Space Frame

A load bearing structure of struts and stays.

Space Lattice

(1) Either an alternative term for crystal lattice or a notation system for defining the location of atoms on the crystal lattice. See *Bravais Lattice*. (2) A regular, periodic array of points (lattice points) in space that represents the locations of atoms of the same kind in a perfect crystal. The concept may be extended, where appropriate, to crystalline compounds and other substances, in which case the lattice points often represent locations of groups of atoms of identical composition, arrangement, and orientation. See also the terms *lattice* and *unit cell*.

Space Processing

The carrying out of various processes on materials aboard orbiting spacecraft is known as space processing. Until the space age, the Earth's gravity had always been considered a constant in the fluid-flow equations that govern heat and mass transport and materials processing. When the space shuttle became operational in the early 1980s, the potential benefits of suppressing the acceleration of gravity in certain processes began to be seriously considered. There have been numerous flight opportunities for microgravity experimentation.

S

Protein Crystal Growth

The importance of crystallography as a mechanism for determining three-dimensional structure of complex macromolecules has placed new demands on the ability to grow large (approximately 0.5 mm on a side), highly ordered crystals of a vast variety of biological macromolecules to obtain high-resolution x-ray diffraction data.

The growth of protein crystals in reduced gravity has the potential advantages of (1) the ability to suspend the growing crystals in the growth solution to provide a more uniform growth environment and (2) the ability to reduce the convective mass transport so that growth can take place to a diffusion-control led environment. The effect of convection on the growth of crystals is not well understood, but it is generally accepted that unsteady growth conditions that can result from convective flows are harmful to crystal growth.

Attempts to grow protein crystals in space produce mixed results. Sometimes no crystals or crystals that are inferior to those grown on Earth are produced. However, occasionally, the space-grown crystals are larger and better ordered than the best ever grown on Earth. In fact, the improvement in internal order obtained in protein growth in reduced gravity can be so dramatic as to allow structure to be solved or refined to higher resolution than is possible by using the diffraction data from the best available Earth-grown crystals.

There is still the question of why attempts to grow protein crystals in space produce superior results only part of the time. (It should be remembered that many unreported experiments on the ground are not successful either.) One possible explanation is that the growth process is developed and optimized on the ground before committing the experiment to flight. However, the conditions that are optimum under normal gravity may not take advantage of the microgravity environment. Therefore, it may be necessary to actually develop the optimal growth processes in space to improve the yield of protein crystal growth experiments there.

Electronic and Photonic Materials

Single-crystalline materials suitable for electronic and photonic applications have received much attention as candidates for microgravity processing for several reasons. These are critical, high-value materials whose applications demand extreme control of composition, purity, and defects. Despite the rapid advances made in electronic materials, progress on many fronts is still limited by available materials. Gravity-driven flows certainly influence mass transport in growth processes. Even though the primary purpose of most of the space processing with these materials has been to gain insight and understanding that can be used in Earth-based processing, limited production of certain specialty materials in space is a possibility if it turns out that there is no Earth-based alternative.

Vapor Growth

Several vapor crystal growth experiments on the shuttle produced some interesting results that are not at all understood. An example is the growth of unseeded germanium-selenium (GeSe) crystals by physical vapor transport using an inert noble gas as a buffer to a closed tube. When this is done on the ground, many small crystallites form a crust inside the growth ampoule at the cold end. Growth in space produces dramatically different results; The crystals apparently nucleate away from the walls and grow as thin platelets, which eventually become entwined with one another, forming a web that is loosely contained by the tube. Even more striking is the appearance of the surfaces of the space-grown crystals. The surfaces are

mirrorlike and almost featureless, exhibiting only a few widely spaced growth terraces. By contrast, crystallites grown on the ground under identical thermal conditions have many pits and irregular, closely spaced growth terraces.

Another example is the growth of $\text{Hg}_{0.4}\text{Cd}_{0.5}\text{Te}$ by closed-tube chemical vapor deposition on mercury-cadmium-tellurium (HgCdTe) substrates using mercuric iodide (HgI_2) as a transport agent. Again, considerable improvements in the space-grown samples are observed, relative to those grown on the ground, in terms of surface morphology, chemical microhomogeneity, and crystalline perfection.

In the growth of thin films of copper phthalocyanine on copper substrates by physical vapor deposition, a dramatic difference is found in the appearance and morphology of the space-grown film as compared with the films produced on the ground. Scanning electron microscopy reveals a close-packed columnar structure for the space-grown films, roughly resembling a thick pile carpet. The ground-grown samples have a lower-density, randomly oriented structure that resembles a shag carpet.

Mercuric iodide crystals grown during orbital flight by physical vapor transport exhibit sharp, well-formed facets indicating good internal order. This is confirmed by gamma-ray rocking curves, which are approximately 1/3 the width of those taken on samples grown on the ground. Both electron and hole mobility are significantly enhanced in the flight crystals.

Solution Growth

Triglycine sulfate crystals can be grown from solution during orbital flight by using a novel cooled sting method. Supersaturation is maintained by extracting heat through the seed mounted on a small heat pipe, which in turn is attached to a thermoelectric device. Growth under diffusion-control transport conditions may avoid liquid and gas inclusions, the most common type of defect in solution-grown crystals, which are believed to be caused by unsteady growth conditions resulting from convective flows.

This growth technique has produced crystals of exceptional quality. The usual growth defects in the vicinity of the seed that forms during the transition from dissolution to growth (the so-called ghost of the seed) are notably absent. High-resolution x-ray topographs taken with synchrotron radiation indicated a high degree of perfection. In pyroelectric detection for far-infrared radiation, the detectivity of the space-grown crystal is significantly higher than the seed crystal and the Q (ratio of energy stored to energy loss per cycle) is more than doubled.

Metallic Alloys and Composites

Processing of metallic alloys and composites in space has been carried out to study dendrite growth, monotectic alloys, liquid-phase sintering, and electrodeposition.

Dendrite Growth

The microgravity environment provides an excellent opportunity to carry out critical tests of fundamental theories of solidification without the complicating effects introduced by buoyancy-driven flows. For example, one investigator carried out a series of experiments to elucidate dendrite growth kinetics under well-characterized diffusion-controlled conditions in pure succinonitrile. This constituted a rigorous test of various nonlinear dynamical pattern formation theories, which provide the basis for the prediction of the microstructure and physical properties achieved in a solidification process.

Comparison of dendrite tip velocities, measured as a function of undercooling over a range from 0.05°C to 1.5°C with ground-based measurements, shows that affects convection are more significant at the smaller undercoolings and are still important up to undercoolings as large as 1.3 K. Even in microgravity, there is a slight departure in the data at the smallest undercooling, which is attributed to the residual acceleration of the spacecraft. These data also allow the determination of the scaling constant important in the selection of the dynamic operating state, which the present theories have been unable to provide.

Monotectic Alloys

Some of the first microgravity experiments and metallurgy were attempts to form fine dispersions in monotectic alloys, that is, alloy systems that have liquid-phase immiscibilities. Attempts to solidify such alloys from the melt in normal gravity always result in macroscopic segregation because the densities of the two liquid phases are invariably different. It was thought that this phase separation could be avoided in microgravity and intimate mixtures of the two phases would result that might have interesting and unusual properties.

Liquid-Phase Sintering

Composites formed by liquid-phase sintering have many commercial applications, from cutting tools to electrical switch contacts. Fine particles of the more refractory phase are mixed with particles of a lower-melting material, which, when melted, forms a matrix to bind the nonmelting particles together. The system is stabilized during the sintering process by using a large volume fraction (80%–85%) of non-melting particles to support the structure while the molten phase interpenetrates the intergranular spaces. Fortunately, for many applications it is desirable to have a large volume fraction of the more refractory phase. However, there are some applications where there is a requirement to increase the volume fraction of the matrix material to amplify its properties. Space processing can be used to prepare composites (such as tungsten particles in a copper–nickel matrix, cobalt particles in a copper matrix, and iron particles in a copper matrix) with host-material volume fractions ranging from 30% to 50%, to increase the sintering time, and to provide valuable insight into evolution of pores and other defects that occur and sintered products produced on Earth.

Electrodeposition

Electrodeposition experiments in reduced gravity have produced some intriguing results. With higher current densities than can normally be used on Earth, nickel with a nanocrystalline structure can be deposited on gold substrates. Attempts to duplicate this result in normal gravity by the use of convectively stable geometries and porous media have not been successful. It is speculated that the morphology of the hydrogen bubbles that form on the cathode in microgravity somehow promotes the formation of nickel hydride, which produces a nanocrystalline structure.

Attempts have been made to codeposit diamond dust with copper, and small particles of Co_2C_3 with cobalt, to form cermets that would be extremely hard and wear resistant. A ground-based technique for depositing a bonelike hydroxyapatite coating on prosthetic implants, which is based on this work, has significantly better adhesion than currently available coatings. Another derivative of this work is a plating process using Cr(III), which poses significantly fewer environmental problems than the common Cr(VI) process.

Spacer Strip

A metal strip or bar inserted in the root of a joint prepared for groove welding to serve as a backing and to maintain root opening throughout the course of the welding operation.

Spacing (Lattice Planes)

See *interplanar distance*.

Space Drill

See preferred term *flat drill*.

Spalling (Ceramics)

(1) The cracking or rupturing of a refractory unit, which usually results in the detachment of a portion of the unit. (2) A defect characterized by separation of the porcelain enamel from the aluminum base metal without apparent external cause. Spalling can result from the use of improper alloys or enamel formulations, incorrect pretreatment of the base metal, or faulty application and firing procedures.

Spalling (Metals)

(1) Separation of particles from a surface in the form of flakes. The term spalling is commonly associated with rolling-element bearings and with gear teeth. Spalling is usually a result of subsurface fatigue and is more extensive than pitting. (2) In *tribology*, the separation of macroscopic particles from a surface in the form of flakes or chips, usually associated with rolling-element bearings and gear teeth, but also resulting from impact events. (3) The spontaneous chipping, fragmentation, or separation of a surface or surface coating. (4) A chipping or flaking of a surface due to any kind of improper heat treatment or material dissociation.

Spalls

The primary cause of premature failures of forged hardened steel rolls. Spalls are sections that have broken from the surface of the roll. In nearly all cases, they are observed in the outer hardened zone of the body surface, and they generally exhibit well-defined fatigue beach marks. The most common spalls are the circular spall and the line spall. Circular spalls exhibit subsurface fatigue marks and a circular, semicircular, or elliptical pattern. They are generally confined to a particular body area. A line spall has a narrow width of subsurface fatigue that extends circumferentially around the body of the roll. Most line spalls originate at or beneath the surface in the outer hardened zone.

Spangle

The characteristic crystalline form in which a hot dipped zinc coating solidifies on steel strip, especially galvanized.

Spark

A series of electrical discharges, each of which is oscillatory and has a comparatively high maximum instantaneous current resulting from the breakdown of the analytical gap or the auxiliary gap, or both, by electrical energy stored in high-voltage in capacitors.

S

Each discharge is self-initiated and is extinguished when the voltage across the gap, or gaps, is no longer sufficient to maintain it.

Spark Erosion

See *electrical pitting*.

Spark Machining

Metal removal by repeatedly striking an electric arc against the component to remove material by melting and vaporization. Usually, the component is submerged in paraffin or a similar medium during machining and individual arc strikes are very small. The technique is useful for very hard materials or for holes which are of complex shape. The component is usually the anode and the tool the cathode.

Spark Sintering

In powder metallurgy, a pressure sintering or hot pressing method that provides for the surface activation of the powder particles by electric discharges generated by a high alternating current applied during the early stage of the consolidation process.

Spark Source Mass Spectrometry

An analytical technique in which a high-voltage spark in a vacuum is used to produce positive ions of a conductive sample material. The ions are injected into a mass spectrometer, and the resulting spectrum is recorded on a photographic plate or measured using an electronic detector. The position of a particular mass spectral signal determines the element and isotope, and the intensity of the signal is proportional to the concentration.

Spark Testing

A method used for the classification of ferrous alloys according to their chemical compositions, by visual examination of the spark pattern or stream that is thrown off when the alloys are held against a grinding wheel rotating at high speed.

Spatial Grain Size

The average size of the three-dimensional grains in polycrystalline materials as opposed to the more conventional grain size determined by a simple average of observations made on a cross section of the material.

Spatial Resolution

A measure of the ability of an imaging system to represent fine detail; the measure of the smallest separation between individually distinguishable structures. See also *resolution*.

Spatter

The metal particles expelled during arc or gas welding. They do not form part of the weld.

Spatter Loss

The metal lost due to *spatter*.

Specific Adhesion

Adhesion between surfaces that are held together by the valence forces of the same type as those that give rise to cohesion.

Specific Energy

In cutting or grinding, the energy expended or work done in removing a unit volume of material.

Specific Gravity (Gases)

The ratio of the density of a gas to the density of dry air at the same temperature and pressure.

Specific Gravity (Solids and Liquids)

The ratio of the density of a material to the density of substandard material, such as water, at a specified temperature. Also known as relative density.

Specific Heat

(1) The ratio of the amount of heat required to raise a mass of material 1° in temperature to the amount required to raise an equal mass of a reference substance, usually water, 1° in temperature; both measurements are made at a reference temperature, usually at constant pressure, or constant volume. (2) The quantity of heat required to raise a unit mass of a homogeneous material one degree in temperature in a specified way; it is assumed that during the process no phase or chemical change occurs.

Specific Humidity

In a mixture of water vapor and air, the mass of water vapor per unit mass of moist air.

Specific Power

Same as *unit power*.

Specific Pressure

In powder metallurgy, the pressure applied to a green or sintered compact per unit of area of punch cross section.

Specific Properties

Material properties divided by material density.

Specific Resistance Resistivity

The electrical resistance of unit length of unit cross-section of material. Measured in microhm centimeters.

Specific Sliding

The ratio of the algebraic difference between the surface velocities of two bodies in relative motion to their sum.

Specific Surface

The surface area of a powder expressed in square centimeters per gram of powder or square meters per kilogram of powder.

Specific Viscosity

The relative viscosity of a solution of known concentration of a polymer minus one. It is usually determined for a low concentration of the polymer.

Specific Volume

The volume of a substance per unit mass; the reciprocal of the density.

Specific Wear Rate

In journal bearings, the proportionality constant K in the equation:

$$h = Kpyt$$

where

h is the radial wear in the bearing

p is the apparent contact pressure

y is the velocity of the journal

t is the sliding time

The constant K has also been called the *wear factor*, but there are other definitions for the term wear factor that do not necessarily refer to journal bearings or derive their meanings from the above equation.

Specimen

A test object, often of standard dimensions and/or configuration, that is used for destructive or nondestructive testing. One or more specimens may be cut from each unit of a *sample*.

Specimen Chamber (Electron Optics)

The compartment located in the column of the electron microscope in which the specimen is placed for observation.

Specimen Charge (Electron Optics)

The electrical charge resulting from the impingement of electrons on a non-conducting specimen.

Specimen Contamination (Electron Optics)

The contamination of the specimen and caused by the condensation upon it of residual vapors in the microscope under the influence of electron bombardment.

Specimen Distortion (Electron Optics)

A physical change in the specimen caused by desiccation or heating by the electron beam.

Specimen Grid

See *specimen screen*.

Specimen Holder (Electron Optics)

A device that supports the specimen and specimen screen in the correct position in the specimen chamber of the microscope.

Specimen Screen (Electron Optics)

A disk of fine screen, usually 200-mesh stainless steel, copper, or nickel, that supports the replica or specimen support film for observation in the microscope.

Specimen Stage

The part of the microscope that supports the specimen holder and the specimen in the microscope and can be moved in a plane perpendicular to the optic axis from outside the column.

Specimen Strain

A distortion of the specimen resulting from stresses occurring during metallographic preparation or observation. In electron metallography, strain may be caused by stretching during removal of a replica or during subsequent washing or drying.

Spectral Background

In spectroscopy, a signal obtained when no analyte is being introduced into the instrument, or a signal from a species other than that of the analyte.

Spectral Distribution Curve

The curve showing the absolute or relative radiant power emitted or absorbed by a substance as a function of wavelength, frequency, or any other directly related variable.

Spectral Line

A wavelength of light with a narrow energy distribution or an image of a slit formed in the focal plane of a spectrometer or photographic plate that has a narrow energy distribution approximately equal to that formed by monochromatic radiation.

Spectral Order

The number of the intensity of a given line from the directly transmitted or specularly reflected light from a *diffraction grating*.

Spectrochemical (Spectrographic, Spectrometric, Spectroscopic) Analysis

The determination of the chemical elements or compounds in a sample qualitatively, semiquantitatively, or quantitatively by measurements of the wavelengths and intensities of spectral lines produced by suitable excitation procedures and dispersed by a suitable optical device.

Spectrogram

A photographic or graphic record of a spectrum.

S

Spectrograph

(1) An optical instrument with an entrance slit and dispersing device that uses photography to record a spectral range. The radiant power passing through the optical system is integrated over time, and the quantity recorded as a function of radiant energy. (2) An instrument for producing and displaying the spectrum of radiation emitted by a material when excited by, for example, an electric arc. It can be used for the analysis of metals. Where the instrument measures the intensity of the omission may be termed a *spectrometer*.

Spectrometer

An instrument with an entrance slit, a dispensing device, and one or more exit slits, with which measurements are made at selected wavelengths within the spectral range, or by scanning over the range. The quantity detected is a function of the radiant power.

Spectrophotometer

A spectrometer that measures the ratio (or a function of the ratio) of the intensity of two different wavelengths of light. These two beams may be separated in terms of time or space, or both.

Spectrophotometry

A method for identification of substances and determination of their concentration by measuring light transmittance in different parts of the spectrum.

Spectroscope

An instrument that disperses radiation into a spectrum for visual observation.

Spectroscopy

The branch of physical science treating the theory, measurement, and interpretation of spectra.

Spectrum

The ordered arrangement of electromagnetic radiation according to wavelength, wave number, or frequency.

Specular Reflection

The condition in which all the incident light is reflected at the same angle as the angle of the incident light relative to the normal at the point of incidence. The reflection surface then appears bright, or mirrorlike, when viewed with the naked eye. Sometimes termed regular reflection.

Specular Transmittance

The transmittance value obtained when the measured radiant energy in *emission spectroscopy* has passed from one source to the receiver without appreciable scattering.

Speculum Metal

An alloy formally used for mirrors and in optical instruments. It contains 65%–67% copper, the balance tin. It takes a beautiful polish

and is hard and tough. An old Roman mirror contained about 64% copper, 19% tin, and 17% lead; and an Egyptian mirror contained 85% copper, 14% tin, and 1% iron. The old Greek mirrors were carefully worked out with 32% tin and 68% copper. They had 70% of the reflecting power of silver, with a slight red excess of reflection that gave a warm glow, without the blue of nickel or antimony. This alloy is now plated on metals for reflectors. A modern telescope mirror contained 70% copper and 30% tin. **Chinese speculum** contains about 8% antimony and 10% tin. Speculum plate, which has been advocated by the Tin Research Institute for electroplating, to give a hard, white, corrosion-resistant surface for food processing equipment and optical reflectors, has 55% copper and 45% tin. It is harder than nickel and retains its reflectivity better than silver.

Speed of Travel

In welding, the speed with which a weld is made along its longitudinal axis, usually measured in meters per second or inches per minute.

Speiss

Metallic arsenides and antimonides that result from smelting metal ores such as those of cobalt or lead.

Spelter

(1) Crude zinc obtained in smelting zinc ores. (2) Brass for brazing or, less commonly, as a cheap alternative to bronze for sculptures.

Spelter Solder

A brazing filler metal of approximately equal parts of copper and zinc.

SPF

See *superplastic forming*.

Spherical Aberration

A lens defect in an optical microscope in which image-forming rays passing through the outer zones of the lens focus at a distance from the principal plane different from that of the rays passing through the center of the lens. See also *aberration* and *chromatic aberration*.

Spherical Bearing

A bearing that is self-aligning by virtue of its partially spherical form.

Spherical Powder

A powder consisting of ball-shaped particles.

Spherical Roller Bearing

(1) A spherical bearing containing rollers. (2) A roller bearing containing barrel-shaped or hour glass-shaped rollers riding on spherical (concave or convex) races to provide self-aligning capability.

Spheroidal Graphite

(1) Graphite of spheroidal shape with a polycrystalline radial structure. This structure can be obtained, for example, by adding cerium or magnesium to the melt. See also *ductile iron* and *nodular graphite*. (2) Graphite, in cast iron, having a spherical rather than a flake shape. See *cast iron*.

Spheroidal Powder

A powder consisting of oval or rounded the particles.

Spheroidite

An aggregate of iron or alloy carbides of essentially spherical shape dispersed throughout a matrix of *ferrite*.

Spheroidized Carbide

Carbide in steel that has become spherical in shape as a result of the heating. See *steel*.

Spheroidized Structure

A microstructure consisting of a matrix containing spheroidal particles of another constituent.

Spheroidizing

Heating and cooling to produce a spheroidal or globular form of carbide in steel. Spheroidizing methods frequently used are:

1. Prolonged holding at a temperature just below A_{c1} .
2. Heating and cooling alternatively between temperatures that are just above and just below A_{c1} .
3. Heating to a temperature above A_{c1} or A_{c3} and then cooling very slowly in the furnace or holding at a temperature just below A_{c1} .
4. Cooling at a suitable rate from the minimum temperature at which all carbide is dissolved to prevent the re-formation of a carbide network, and then reheating in accordance with method one or two above. (Applicable to hypereutectoid steel containing a carbide network.) See *steel*.

Spherulite

A rounded aggregate of radiating laminar crystals with appearance of a pom-pom in plastics. Spherulites contain amorphous material between the crystals and usually impinge on one another, forming polyhedrons. Spherulites are present in most crystalline plastics and may range in diameter from a few tenths of a micron to several millimeters.

Spherulitic Graphite Cast Iron

Same as *ductile cast iron*.

Spider

In a plastic molding press, that part of an ejector mechanism that operates the ejector pins. In extrusion, the membranes supporting a mandrel within the head/die assembly.

Spider Die

Same as *porthole die*.

Spiegel, Spiegeleisen

Ferromanganese master alloys used in the final stages of steel production. Where they are differentiated the former has about 20%–30% manganese and 5% carbon, remainder iron, while the latter is similar but with about 5%–20% manganese. See *pig iron*.

Spiking

In electron beam welding and laser welding, a condition where the depth of penetration is nonuniform and changes abruptly over the length of the weld.

Spin

In bearings, rotation of a rolling element about an axis normal to the contact surfaces. See also *rolling* (pure rolling with no sliding and no spin) and *sliding*.

Spindle

(1) Shaft of a machine tool in which a cutter or grinding wheel may be mounted. (2) Metal shaft to which a mounted wheel is cemented.

Spindle Oil

An oil of low viscosity used to lubricate high-speed light spindles.

Spinel

Spinel is any of a family of important AB_2O_4 oxide minerals, where A and B represent cations with a simple cubic crystal lattice. Spinel minerals are widely distributed in the Earth, in meteorites, and in rocks from the moon. The ideal spinel formula is $MgOAl_2O_3$ or $MgAl_2O_4$. Spinel has a melting point of 2135°C and the mineral is found in small deposits. It is formed by solid-state reaction between MgO and Al_2O_3 and is an excellent refractory showing high resistance to attack by slags, glass, etc.

$MgOAl_2O_3$ or $MgAl_2O_4$ compound itself, is refractory and chemically near-neutral. Magnesium aluminate spinels are used as an addition to fired magnesia refractory bricks to improve thermal shock resistance. Lithium-based spinels are candidate materials for rechargeable lithium batteries.

High-purity spinel is a chemically derived spinel powder made by the co-precipitation of magnesium and aluminum complex sulfates, with subsequent calcination to form the oxide compound. Purities range from 99.98% to 99.995%. The ceramic powders prepared by this process can be hot-pressed into transparent window materials with exceptional infrared transmission range.

Applications

The major ceramic applications for spinels are the magnetic ferrosinels (ferrites), chromite brick, and spinel colors. Magnetic recording tape coated with $\alpha\text{-Cr}_2\text{O}_3$ is a relatively recent development. It is also used as a porous protective coating in oxygen sensors for automotive emission controls.

The material is available as fused spinel in special refractory applications and also in a special particle shape and distribution for

S

flame and plasma-arc spraying. The magnetic spinels are of special importance because of the wide-spread interest and application of the ceramic ferrosinels (ferrites). Two classes of ferrosinels occur: magnetic and nonmagnetic.

The magnetic are related to the inverse structure in the nonmagnetic to the normal structure.

Spin Glass

One of a wide variety of materials that contain interacting atomic magnetic moments and also possess some form of disorder, in which the temperature variation of the magnetic susceptibility undergoes an abrupt change in slope at a temperature generally referred to as the freezing temperature.

Spinneret

A type of extrusion die for plastics that consists of a metal plate with many tiny holes, through which a plastic mesh is forced, to make fine fibers and filaments. Filaments may be hardened by cooling in air, water, and so forth, or by chemical action.

Spinning

The forming of a seamless hollow metal part by forcing a rotating blank to conform to a shaped mandrel that rotates concentrically with a blank. In the typical application, a flat-rolled metal blank is forced against the mandrel by a blunt, rounded tool; however, other stock (notably, welded or seamless tubing) can be formed. A roller is sometimes used as the working end of the tool.

Spinning

A manufacturing process in which sheet or plate material is rapidly rotated and forced by a non-cutting tool against a shaped former. The variations range from the simplest where a plain shaping tool is handheld to high powered systems where a roller head tool is carried on a powered carriage; the latter may be termed *flow spinning*.

Spinodal Curve

A graph of the realizable limit of the supersaturation of a solution. See also *spinodal structure*.

Spinodal Hardening

See *aging*.

Spinodal Structure

A fine, homogeneous mixture of two phases that form by the growth of composition waves in a solid solution during suitable heat treatment. The phases of a spinodal structure differ in composition from each other and from the parent phase, but have the same crystal structure as the parent phase. Spinodal structures are resolvable only at high magnifications such as made possible by *transmission electron microscopy*.

Spin Wave

A sinusoidal variation, propagating through a crystal lattice, of that angular momentum associated with magnetism (mostly spin angular momentum of the electrons). See also *spin glass*.

Spin Welding

Same as friction welding particularly when applied to plastics.

Spiral-Flow Test

A method for determining the flow properties of a thermoplastic resin in which the resin flows along the path of a spiral cavity. The length of the material that flows into the cavity and its weight gives a relative indication of the flow properties of the resin.

Spiral Mold Cooling

A method of cooling injection molds or similar molds for forming plastics in which the cooling medium flows through a spiral cavity in the body of the mold. In injection molds, the cooling medium is introduced at the center of the spiral, near the sprue section, because more heat is localized in this section.

Spiral Welded Tube

Tube formed from strip rolled to a helix and welded on the spiral interface between the edges.

Spit

See preferred term *flash*.

Splash Lines

Damaging or unsightly material on the surface or in the interface of spot or seam welds, etc., caused by the ejection of material during welding.

Splash Lubrication

A system of lubrication in which the lubricant is splashed onto the moving parts.

Splat Casting

Dropping small quantities of molten metal onto a cold metal surface to achieve very rapid rates of cooling. A variation of the technique runs a thin stream of molten metal onto a cold metal wheel.

Splat Powder

A rapidly cooled or quenched powder whose particles have a flat shape and a small thickness compared to other dimensions. Similar to *flake powder*.

Splat Quenching

The process of producing splat powder.

Splay

The tendency of a rotating drill bit to drill off-center, out-of-round, non-perpendicular holes.

Splay (Plastics)

A fanlike surface defect near the gate on a plastic part.

Splay Lines

Lines found in a plastic part after molding, usually due to the flow of material in the mold. Sometimes called *silver streaking*.

Splice

The joining of two ends of glass fiber yarn or strand used for reinforcing plastics, usually by means of an air-drying adhesive.

Splicing

The joining of two multiply stranded ropes or cables by intertwining the individual strands of each into the other.

Spline

Any of a series of longitudinal, straight projections on a shaft that fit into slots on a mating part to transfer rotation to or from the shaft.

Split Die

A die made of part that can be separated for ready removal of the workpiece. Also known as segment die.

Split Pipe Backing

Backing in the form of a pipe segment used for welding round bars.

Split Punch

A segmented punch or a set of punches in a powder metallurgy forming press that allow(s) a separate positioning for different powder fill heights and compact levels in dual-step and multistep parts. See also *stepped compact*.

Split-Ring Mold

A mold for forming plastics in which a split-cavity block is assembled in a chase to permit the forming of undercuts in a molded plastic piece. These parts are ejected from the mold and then separated from the piece.

Split Seal

A seal that has its primary sealing elements split in a plane parallel to the axis of the shaft such that, instead of the rings being continuous, they are essentially two semicircles. Modified designs of lip seals feature units with a single lip separation and with one or more separations of the metallic stiffening mechanisms.

Spodumene

A mineral of composition $\text{Li}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$, with some potassium and sodium oxides. It is the chief ore of the metal lithium, but it requires a higher temperature for sintering than lepidolite, and the sinter is more difficult to leach. **Lithospar** is a name for feldspar and

spodumene from North Carolina. In Germany lithium is obtained from the lithium mica **zinnwaldite**, which is a mixture of potassium–aluminum orthosilicate and lithium orthosilicate with some iron, and contains less than 3% Li_2O .

Sponge

The cellular skeleton of a marine animal of the genus *Spongia*, of which there are about 3000 known species, only 13 of which are of commercial importance. It is employed chiefly for wiping and cleaning, as it will hold a great quantity of water in proportion to its weight, but it also has many industrial uses such as applying glaze to pottery. Sponges grow like plants, attached to rocks on the sea bottom. They are prepared for use by crushing to kill them, scraping off the rubbery skin, macerating in water to remove the gelatinous matter, and bleaching in the sun.

The prepared sponge is an elastic, fibrous structure chemically allied to silk. It has sievelike membranes with small pores leading into pear-shaped chambers. The best sponges are spheroidal, regular, and soft. Commercial sponges for the U.S. market must have a diameter of 11.4 cm or more. Most of the Florida sponges are the **sheepswool sponge**, use for cleaning and industrial sponging. The **Rock Island sponge**, from Florida, and the **Key wool sponge** are superior in texture and durability to the **Bahama wool sponge**, which is coarser, more open, and less absorbent. The **Key yellow sponge** is the finest grade. The **grass sponge**, is inferior in shape and texture. The fine **honeycomb sponge**, of the Mediterranean Sea, is of superior grade and has been preferred as a bath sponge. The **Turkey cup sponge** is rated as the finest, softest, and most elastic of the sponges, but the larger of the zimocca sponges are too hard for surgical use and are employed for industrial cleaning. Sponges for industrial and household uses have now been largely replaced by foamed rubbers and plastics.

Sponge

A form of metal characterized by a porous condition that is the result of the decomposition or reduction of a compound without fusion. The term is applied to forms of iron, titanium, zirconium, uranium, plutonium, and the platinum group metals.

Sponge Effect

See *squeeze effect*.

Sponge Iron

Iron made from ferrous sand and pressed into briquettes, which can be charged directly into steel furnaces instead of pig iron. It was originally made on a large scale in Japan where only low-grade sandy ores were available. Sponge iron is made by charging the sand continuously into a rotary furnace to drive off the light volatile products and reduce the iron oxide to metallic iron, which is passed through magnetic separators, and the finely divided iron briquetted. Unbriquetted sponge iron, with a specific gravity of 2, is difficult to melt because of the oxidation, but briquetted material, with a specific gravity of 6, can be melted in electric furnaces. Sponge iron, to replace scrap in steelmaking, is also made from low-grade ores by reducing the ore with coke-oven gas or natural gas. It is not melted, but the oxygen is driven off, leaving a spongy, granular product. As it is very low in carbon, it is also valuable for making high-grade alloy steels.

S

A form of sponge iron employed as a substitute for lead for coupling packings was made in Germany under the name of **sinterit**. The reduction is carried out in a reducing atmosphere at a temperature of 1200°C–1350°C, instead of heating the iron oxide with carbon. Since the porous iron corrodes easily, it is coated with asphalt for packing use. **Iron sponge**, employed as a purifier for removing sulfur and carbonic acid from illuminating gas, is a sesquioxide of iron obtained by heating together iron ore and carbon. It has a spongy texture and is filled with small cells.

Sponge Iron Powder

Ground and sized sponge iron that may have been purified or annealed or both.

Sponge Titanium Powder

Ground and sized titanium sponge. See also *Kroll process*.

Spongy

A porous condition in metal powder particles usually observed in reduced oxides.

Spool

A type of weld filler metal package consisting of a continuous length of electrode wound on a cylinder (called the barrel) which is flanged at both ends. The flange extends below the inside diameter of the barrel and contains a spindle hole.

Spot Drilling

Making an initial indentation in a work surface, with a drill, to serve as a sintering guide in a subsequent machining process.

Spotfacing

Using a rotary uneven staining of metal by entrapment, hole-piloted end-facing tool to produce a flat surface normal to the axis of rotation of the tool on or slightly below the workpiece surface.

Spot Test

A test in which spots of chemical reagents applied to the test surface produce reactions indicative of the composition.

Spotting Out

Delayed, uneven staining of metal by entrapment of chemicals during the finishing operation.

Spot Weld

A weld made between or upon overlapping members in which coalescence may start and occur on the faying surfaces or may proceed from the surface of one member. The weld cross section is approximately circular. See the term *resistance spot welding*.

Spot Welding

(1) Welding of the lapped parts in which fusion is confined to a relatively small circular area. It is generally resistance welding, but may also be gas tungsten-arc, gas metal-arc, or submerged-arc welding. (2) A resistance welding process in which the components, usually sheet, are clamped between two electrodes supplying heating current. The weld formed is approximately the size of the electrodes, or the smaller of them if they differ. (3) Any localized weld formed by any process. See the term *resistance spot welding*.

Spragging

Intermittent motion arising from design features that allow an increase in tangential force or displacement to produce an increase in normal force.

Spray Angle

In thermal spraying, the angle of particle approach, measured from the surface of the substrate to the axis of the spray nozzle.

Spray Deposit

A coating applied by any of the thermal spray methods. See also *thermal spraying*.

Spray Distance

In thermal spraying, the distance maintained between the gun nozzle and the substrate surface during spraying.

Spray Drier

A large vessel into which a slurry containing metal or ceramic powders is sprayed through orifices in a stationary or revolving head and thrown as droplets into a stream of heated air which dries them. The dried droplets are typically tiny agglomerates, often in hollow bead form, hence free-flowing.

Spray Drying

A powder-producing process in which a slurry of liquids and solids or a solution is atomized into droplets and a chamber through which heated gases, usually air, are passed. The liquids are evaporated from the droplets and the solids are collected continuously from the chamber. The resulting powder consists of free-flowing, spherical agglomerates.

Sprayed-Metal Molds

Molds for forming plastics made by spraying molten metal onto a master until a shell of predetermined thickness is achieved. The shell is then removed and backed with plaster, cement, casting resin, or other suitable material. Used primarily as a mold in the sheet-forming process.

Spraying Sequence (Thermal Spraying)

The order in which different layers of similar or different materials are applied in a planned relationship, such as overlapped, superimposed, or at certain angles.

Spray Lay-Up

A wet lay-up for processing of reinforced plastics in which a stream of chopped fibers (usually glass) is fed into a stream of liquid resin in a mold. The direction of the fibers is random, as opposed to the mats or woven fabrics that can be used in hand lay-up. See also *hand lay-up* and *wet lay-up*.

Spray Metal Forming

Spray metal forming is a rapid solidification technology for producing semifinished tubes, billets, plates, and simple forms in a single integrated operation. In contrast to other powder metallurgy processes, spray metal forming offers the distinct advantage of skipping the intermediate steps of atomization and consolidation by atomizing and collecting the spray in the form of a billet in a single operation. Also, the elimination of powder handling reduces oxide content and enhances ductility.

The Process

Spray forming involves converting a molten metal stream into a spray of droplets by high-pressure gas atomization. The droplets cool rapidly in flight and ideally arrive at a collector plate with just enough liquid content to spread and completely wet the surface. The metal then solidifies into one almost fully dense preform with a very fine, uniform microstructure. Steel, copper, nickel-based superalloys, and aluminum alloys have been successfully spray-formed. These billets are combined, in the downstream manufacturing process, with extrusion or forging, and then coupled with high-speed machining to produce components in final form.

Advantages

Rapid solidification processes such as spray metal forming offer some distinct advantages over conventional ingot metallurgy processing. Superior properties due to fine grain sizes; a fine, homogeneous distribution of second-phase precipitates; and the absence of macrosegregation result from cooling rates on the order of 10^3 – 10^5 K/s (gas atomization processes approach 10^6 K/s). The high cooling rate in spray forming is obtained by higher gas-to-metal ratios. In certain alloy systems, a high volume fraction of fine (0.05–0.2 μm) intermetallic dispersoids may be obtained with high gas-to-metal ratios.

Applications

Many different aluminum alloys and SiC-particulate-reinforced aluminum metal-matrix composites have been processed. They include conventional alloys in the 2XXX, 3XXX, 5XXX, 6XXX, and 7XXX series; high-temperature and high-strength alloys; and high-silicon-content alloys. The nonconventional alloys have been developed specifically for spray forming or adapted from alloys developed for rapid solidification rate (RSR) processes such as gas atomization or melt spinning. These alloys have shown superior properties such as wear resistance, room- and high-temperature strength, and creep resistance.

Alloys developed especially for spray forming, such as the ultrahigh zinc content alloys and 7050 aluminum with additional zinc, have been processed. Many of these alloys have been processed with the addition of SiC to improve the stiffness. These alloys have shown superior strength properties over conventionally processed material.

For principal alloy systems originally developed for RSR processing have been extensively spray-formed. These are Al–Fe–V–Si (FVS), Al–Fe–Ce–W (FCW), Al–Ce–Cr–Co (CCC), and Al–Ni–Co (NYC) alloys. To optimize mechanical properties, these alloys were spray-formed over a range of processing parameters. For ultrahigh-temperature aluminum alloys, the melt superheat, or pour temperature, and the gas-to-metal ratio, and the injection of SiC particulate, have the greatest effect on microstructure (e.g., droplet and dispersoid size and volume fraction) and resultant properties.

Uses

Two government-sponsored programs have been completed using spray-formed material to produce components for use in Department of Defense vehicles. The first program produced track pins for advanced tract ground combat vehicles using an ultrahigh-strength aluminum alloy. The second program developed the spray-forming processing parameters to produce an ultrahigh-temperature aluminum alloy for stator vanes in high-performance jet aircraft engines.

The goal of the track pin program was to develop processing that produces an ultrahigh-strength aluminum alloy that can replace the steel currently used in the manufactured pins for tract ground combat vehicles. The objective was to replace the hollow steel pin with a solid aluminum pin that has similar properties. Several alloys were spray-formed, extruded, heat-treated, and tested to determine the tensile strength, ductility, and modulus. The two alloys with the best combination of properties were selected for additional processing. To increase the stiffness, SiC was added during spray forming. The spray-formed ultrahigh-strength alloys have yield strengths in excess of 690 MPa and show good ductility even with the addition of SiC. Track pins have been produced and were successfully tested. The corrosion resistance of these materials is improved by spray forming. The use of the ultrahigh-strength aluminum would result in a weight reduction of over 204.3 kg.

The NYC alloy shows promise for use in static parts of jet engines. The material properties at high temperatures provide an opportunity to replace heavier titanium parts with a lighter-weight aluminum alloy resulting in substantial saving in life-cycle costs.

The high-temperature aluminum alloy has been produced as extrusions and forgings. Machining contractors have developed the most efficient and economical processes to deliver a finished part. The alloy has been extruded and machined into the final component configuration and the alloy has good machining characteristics. Forging trials have shown that the material can be readily deformed offering increased material yield.

Spray Metallizing

See *metallizing*.

Spray Nozzle

In atomizing of metal powders, an orifice through which a molten metal passes to form a stream that can be further disintegrated by a gas, a liquid, or by mechanical means.

Spray Quenching

A quenching process using spray nozzles to spray water or other liquids on a part. The quenched rate is controlled by the velocity and volume of liquid per unit area per unit of time of impingement.

S

Spray Rate

Same as *feed rate*.

Spray Transfer

In consumable-electrode arc welding, a type of metal transfer in which the molten filler metal is propelled across the arc as fine droplets. Compare with *globular transfer* and *short-circuiting transfer*. See also the term *short-circuiting transfer* and *metal transfer*.

Spray Welding

Various processes for producing coatings on metals. The basic characteristic is that the material is initially applied by some metal powder spraying technique and the component is then heated by a flame or other means to cause the deposited powder to fuse to the component.

Spread

The quantity of adhesive per unit joint area applied to an adherend, usually expressed in pounds of adhesive per thousand square feet of joint area.

Spreader

An axial groove in a plain bearing designed to spread oil along the bearing.

Spreader (Plastics)

A streamlined metal block placed in the path of flow of the plastic material in the heating cylinder of extruders and injection molding machines to spread it into thin layers, thus forcing it into intimate contact with the heating areas.

Spreader Pockets

Depressions in a sliding surface designed to distribute lubricant.

Sprengle Explosives

Chlorate compounds that have been rendered reasonably safe from violent explosion by separating the chlorate from the combustible matter. The potassium chlorate, made into porous cartridges and dipped, just before use, in a liquid combustible such as nitrobenzene or dead oil, was called **rack-a-rock**. It is a mixture of 79% chlorate and 21% nitrobenzene. **Rack-a-rock special** contains, in addition, 12%–16% picric acid. Sprengle explosives were formally used as military explosives, are very sensitive to friction and heat, and are now valued only for mining or when it is desired to economize on nitrates.

Sprigs

Pins or rods inserted to strengthen local weak areas of sand molds.

Springback

(1) The elastic recovery of metal after stressing. (2) The extent to which metal tends to return to its original shape or contour after

undergoing a forming operation. This is compensated for by overbending or by a secondary operation of *restriking*. (3) In flash, upset, or pressure welding, the deflection in the welding machine caused by the upset pressure.

Spring Brass

An imprecise term applied to various hard rolled brass alloys but particularly 70% copper, 30% zinc.

Spring Constant

The force required to compress a spring or specimen 25 mm (1 in.) in a prescribed test procedure.

Spring Steel

This is a term applied to any steel used for springs. The majority of springs are made of steel, but brass, bronze, nickel silver, and phosphor bronze are used where their corrosion resistance or electric conductivity is desired. Carbon steels, with from 0.50% to 1.0% carbon, are much used, but vanadium and chromium–vanadium steels are also employed, especially for heavy car and locomotive springs. Special requirements for springs are that the steel be low in sulfur and phosphorus, and that the analysis be uniform. For flat or spiral springs that are not heat-treated after manufacture, hard-drawn or rolled steels are used. These may be tempered in the mill shape. Music wire is widely employed for making small spiral springs. A much-used straight-carbon spring steel has 1% carbon and 0.30%–0.40% manganese, but becomes brittle when overstressed. ASTM carbon steel for flat springs has 0.70%–0.80% carbon and 0.50%–0.80% manganese, with 0.04% max each of sulfur and phosphorus. Motor springs are made of this steel rolled hard to a tensile strength of 1723 MPa. Watch spring steel, for mainsprings, has 1.15% carbon, 0.15%–0.25% manganese, and in the hard-rolled condition, as an elastic limit above 2068 MPa.

Silicon Steels

These are used for springs and have high strength. These steels average about 0.4% carbon, 0.75% silicon, and 0.95% manganese, with or without copper, but the silicon may be as high as 2%. A steel, used for automobile leaf springs and recoil springs, contains 2% silicon, 0.75% manganese, and 0.60% carbon. The elastic limit is 689–2068 MPa, depending on drawing temperature, with a hardness 250–600 Brinell.

Manganese Steels

These steels for automotive springs contain about 1.25% manganese and 0.40% carbon, or about 2% manganese and 0.45% carbon. When heat-treated, the latter has a tensile strength of 1378 MPa and 10% elongation. Part of the manganese may be replaced by silicon and the silicon–manganese steels have tensile strengths as high as 1861 MPa. The addition of chromium or other elements increases ductility and improves physical properties. Manganese steels are deep-hardening but are sensitive to overheating. The addition of chromium, vanadium, or molybdenum widens the hardening range.

Forms

Wire for coil springs ranges in carbon from 0.50% to 1.20%, and in sulfur from 0.028% to 0.029%. Bessemer wire contains too much

sulfur for spring use. Cold working is the method for hardening the wire and for raising the tensile strength.

The highest grades of wire are referred to as music wire. The second grade is called hard-drawn spring wire. The latter is a less expensive basic open-hearth steel with manganese content of 0.80%–1.10%, and an ultimate strength up to 2068 MPa.

Applications

For jet-engine springs and other applications wear resistance to high temperatures is required, stainless steel and high-alloy steels are used. But, while these may have the names and approximate compositions of standard stainless steels, for spring-wire use their manufacture is usually closely controlled. For example, when the carbon content is raised in high-chromium steels to obtain the needed spring qualities, the carbide tends to collect in the grain boundaries and cause intergranular corrosion unless small quantities of titanium, columbium, or other elements are added to immobilize the carbon. Types include Type 302 stainless steel of highly controlled analysis for coil springs. Alloy NS-355 is a stainless steel having a typical analysis of 15.64% chromium, 4.38% nickel, 2.68% molybdenum, 1% manganese, 0.32% silicon, 0.12% copper, with the carbon at 0.14%. The modulus of elasticity is 205,100 MPa at 27°C and 168,000 MPa at 427°C. 17-7 PH stainless steel has 17% chromium, 7% nickel, 1% aluminum, and 0.07% carbon. Wire has a tensile strength up to 2378 MPa. Spring wire for high-temperature coil springs may contain little or no iron. Alloy NS-25, for springs operating at 760°C, contains about 50% cobalt, 20% chromium, 15% tungsten, and 10% nickel, with not more than 0.15% carbon.

Spring Temper

A *temper* of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about two-thirds of the way from *full hard* to *extra spring temper*.

Sprue (Metals)

- (1) The mold channel that connects the *pouring basin* with the runner or, in the absence of a pouring basin, directly into which molten metal is poured. Sometimes referred to as down-sprue or downgate.
- (2) Sometimes used to mean all gates, risers, runners, and similar scrap that are removed from castings after shakeout.

Sprue (Plastics)

A single hole through which thermoset molding compounds are injected directly into the mold cavity.

Spun Parts

Metal spinning, essentially, involves forming flat sheet metal disks into seamless circular or cylindrical shapes. It is a useful processing technique when quantity does not warrant investment needed for draw dies.

The Process

The first step in the spinning process is to produce a form to the exact shape of the inside contours of the part to be made. The form

can be of wood or metal. This form is secured to the headstock of a lathe and the metal blank is, in turn, secured to the form. Manual spinning techniques exist, and mechanical spinning lathes usually can be set up to force the blank against the form mechanically.

In addition to manual or power spinning, hot spinning is sometimes used either to anneal a spun part, eliminating the need to remove a partially formed blank from the lathe, or else to increase the plasticity of the metal being formed. In the latter category, some metals such as titanium or magnesium must be spun hot because their normal room-temperature crystal structure lacks ductility. Heavy parts (up to 122 mm in some cases) can also be spun with increased facility at elevated temperature.

Shapes and Tolerances

Basically, a component must be symmetrical about its axis to be adaptable to spinning. The three basic spinning shapes are the cone, hemisphere, and straight-sided cylinder. The shapes are listed in order of increasing difficulty to be formed by spinning.

Available spinning equipment is the limiting factor in determining the size of parts. Parts can be made ranging in diameter from 25.4 mm to almost 3.6 m. Thickness ranges from 0.010 to 122 mm. Most commonly, spun parts range in thickness from 0.059 to 4.7 mm.

Spun Roving

A heavy, low-cost glass or aramid fiber strand consisting of filaments that are continuous but doubled back on themselves. See also *roving*.

Sputtering

The bombardment of a solid surface with a flux of energetic particles (ions) that results in the ejection of atomic species. The ejected material may be used as a source for deposition. No heat is involved. The ejected atoms are deposited on surrounding surfaces. See also *physical vapor deposition* and the term *secondary ion*.

Sputter Texturing

Texturing of a metal surface improves the bonding of surfacing material to the substrate or the attachment of parts to the textured piece. One of many applications is the texturing of the metal surface of medical hip implants. These devices require an irregular surface to stimulate bone attachment.

Texturing of complex shapes can be improved with a sputter-etching method that uses temporarily attached ceramic particles. By controlling the size and distribution of the ceramic particles, the width and depth of the texture can be regulated.

The first stage of the process is the spraying or dripping of adhesive on the area to be textured. Microspheres of ceramic are forced into the adhesive and the area is heated. The part is then placed in a discharge chamber where it is bombarded with argon ions. This operation produces an etching on the surface of the part not covered by the ceramic spheres. The etch depth is controlled by voltage, current density, and sputtering duration. The adhesive, which is charred by the sputter-etch process, is removed with atomic oxygen in a plasma asher. The brushing away of the ceramic particles reveals a textured surface. See *Ind. Heating*, January, p. 45, 2000.

S

Square Drilling

Making square holes by means of a specially constructed drill made to rotate and also to oscillate so as to follow accurately the periphery of a square guide bushing or template.

Square Groove Weld

A groove weld in which the abutting surfaces are square.

Squaring Shear

A machining tool, used for cutting sheet metal or plate, consisting essentially of a fixed cutting knife (usually mounted on the rear of the bed) and another cutting knife mounted on the front of a reciprocally moving crosshead, which is guided vertically in side housings. Corner angles are usually 90°. See the term *shear* (2).

Squeeze Affect

(1) The production of lubricant from a porous retainer by application of pressure. Also known as sponge effect. (2) The persistence of a film of fluid between two surfaces that approach each other in the direction of their common normal plane.

Squeeze Casting

A hybrid liquid-metal forging process in which liquid metal is forced into a permanent mold by a hydraulic press.

Squeeze-Out

Adhesive pressed out of the bond line due to pressure applied on the adherends.

Squeeze Time

In resistance welding, the time between the initial applications of pressure and current.

Stable

Not liable to change physically or chemically.

Stabilization

In carbon fiber forming, the process used to render the carbon fiber precursor infusible prior to carbonization.

Stabilized Stainless Steel

Austenitic stainless steel containing sufficient quantities of certain elements such as titanium, or niobium (columbium). These combine preferentially with carbon which, in their absence would, upon heating in the 400°C–900°C range, combine with the chromium causing local chromium depletion, particularly at grain boundaries, leading to corrosion problems, for example, after welding. To achieve immunity the alloy addition needs to exceed some level related to the carbon content; typical figures being 10× carbon for niobium and 5× carbon for titanium. Immunity from this form of damage is also achieved by limiting the carbon to less than 0.03% or by quenching the steel from 1050°C or by adding an element, such as molybdenum

at about 3%, which induces a small percentage of ferrite which localizes the carbide precipitation. However, although these latter three treatments confer immunity the term ‘stabilized’ is usually taken to apply steel varieties with a strong carbide formers. See *steel*, *sensitization* and *weld decay*.

Stabilizers

Chemicals used in plastics formulation to help maintain physical and chemical properties during processing and service life. A specific type of stabilizer, known as an ultraviolet stabilizer, is designed to absorb ultraviolet rays and prevent them from attacking the plastic. Heat stabilizers are added to lessen the severity of thermal oxidation processes and their effect on properties.

Stabilizing Gas (Plasma Spraying)

The arc gas, which is ionized to form the plasma. Introduced into the arc chamber tangentially, the relatively cold gas chills the outer surface of the arc stream, tending to constrict the arc, raise its temperature, and force it out of the front anode nozzle in a steady, relatively un-fluctuating stream. See the terms *plasma spraying* and *transferred arc*.

Stabilizing Treatment

(1) Before finishing to final dimensions, repeatedly heating a ferrous or nonferrous part to or slightly above its normal operating temperature and then cooling to room temperature to ensure that there is dimensional stability in service. (2) Transforming retained austenite in quenched hardenable steels, usually by *cold treatment*. (3) Heating a solution-treated stabilized grade of austenitic stainless steel to 870°C–900°C to precipitate all carbon as TiC, NbC, or TaC so that *sensitization* is avoided on subsequent exposure to elevated temperature. (4) Any process intended to stabilize the microstructure, dimensions or other features of a component so that undesirable changes do not occur in subsequent service or treatment. For example, some complex component intended for high-temperature service may be subjected to a pre-service heat treatment at a slightly higher temperature.

Stack Cutting

Thermal cutting of stacked metal plates arranged so that all the plates are severed by a single cut.

Stacking Fault

A defect in the crystal lattice in which the normal stacking arrangement is disrupted with partial dislocations at the perimeter.

Stack Molding (Metals)

A foundry practice that makes use of both faces of a mold section, one face acting as the drag and the other as the cope. Sections, when assembled to other similar sections, form several tiers of mold cavities, all castings being poured together through a common screw.

Stacking Sequence

A description of a laminate that details the orientations of the plies and their sequence in the laminate. See also the terms *laminate* and *quasi-isotropic laminate*.

Stack Welding

Resistance spot welding of stacked plates, all being joined simultaneously.

Stage

A device for holding a specimen in the desired position in the optical path of a microscope.

Staggered-Intermittent Fillet Welding

Making a line of intermittent fillet welds on each side of a joint so that the increments on one side are not opposite those on the other. Contrast with *chain-intermittent fillet welding*.

Staggered-Tooth Cutters

Milling cutters with alternate flutes of oppositely directed helixes.

Staging

Heating a premixed resin system, such as in a *prepreg*, until the chemical reaction (curing) starts, but stopping the reaction before the gel point is reached. Staging is often used to reduce resin flow in subsequent press molding operations.

Staining

Precipitation etching that causes contrast by distinctive staining of microconstituents; different interference colors originate from surface layers of varying thickness. Also known as *color etching*.

Stainless Steel

Stainless steel comprises a large and widely used family of iron-chromium alloys known for their corrosion resistance—notably their “non-rusting” quality. This ability to resist corrosion is attributable to a chromium-oxide surface film that forms in the presence of oxygen. The film is essentially insoluble, self-healing, and nonporous. A minimum chromium content of 12% is required for the formation of the film, and 18% is sufficient to resist even severe atmospheric corrosion. Chromium content, however, may range to about 30% in several other alloying elements, such as manganese, silicon, nickel, or molybdenum, are usually present. Most stainless steels are also resistant to marine atmospheres, fresh water, oxidation at elevated temperatures, and mild and oxidizing chemicals. Some are also resistant to salt water and reducing media. They are also quite heat resistant, some retaining useful strength to 981°C. And some retain sufficient toughness at cryogenic temperatures. Thus, stainless steels are used in a wide range of applications requiring some degree of corrosion and/or heat resistance, including auto and truck trim, chemical and food-processing equipment, petroleum-refining equipment, furnace parts in heat treating hardware, marine components, architectural applications, cookware and housewares, pumps and valves, aircraft and aircraft-engine components, springs, instruments, and fasteners.

The 18-8 chromium-nickel steels were called super stainless steels in England to distinguish them from the plain chromium steels. Today, wrought stainless steels alone include some 70 standard compositions and many special compositions. They are categorized as

austenitic, ferritic, martensitic, or precipitation-hardening (PH) stainless steels, depending on their microstructure or, in the case of the PH, their hardening and strengthening mechanism. There are also many cast stainless steels having these metallurgical structures. They are also known as cast corrosion-resistant steels, cast heat-resistant steels, and cast corrosion- and heat-resistant steels. Several compositions are also available in powder form for the manufacture of stainless steel powder-metal parts.

Fabrication

As with steels in general, the so-called wrought stainless steels come from the melting furnaces in the form of ingot or continuously cast slabs. Ingots require a roughing or primary hot working, which the other form commonly bypasses. All then go through fabricating and finishing operations such as welding, hot and cold forming, rolling, machining, spinning, and polishing. No stainless steel is excluded from any of the common industrial processes because of its special properties; yet all stainless steels require attention to certain modifications of technique.

Hot Working

Hot working is influenced by the fact that many of the stainless steels are heat-resisting alloys. They are stronger at elevated temperatures than ordinary steel. Therefore, they require greater roll and forge pressure, and perhaps less reductions per pass or per blow. The austenitic steels are particularly heat resistant.

Welding

Welding is influenced by another aspect of high-temperature resistance of these metals—the resistance to scaling. Oxidation during service at high temperatures does not become catastrophic with stainless steel because the steel immediately forms a hard and protective scale. But this, in turn, means that welding must be conducted under conditions that protect the metal from such reactions with the environment. This can be done with specially prepared coatings on electrodes, under cover of fluxes, or in vacuum; the first two techniques are particularly prominent. Inert-gas shielding also characterizes widely used processes among which at least a score are now numbered. As for weld cracking, care must be taken to prevent hydrogen absorption in the martensitic grades and martensite in the ferritic grades, whereas a small proportion of ferrite is almost a necessity in the austenitic grades. Metallurgical “phase balance” is an important aspect of welding the stainless steels because of these complications from a two-phase structure. Thus, a minor austenite fraction in ferritic stainless can cause martensitic cracking, while a minor ferrite fraction in austenite can prevent hot cracking. However, the most dangerous aspect of welding austenitic stainless steel is the potential “sensitization” affecting subsequent corrosion.

Machining and Forming

These processes adapt to all grades, and with these major precautions: First, the stainless steels are generally stronger and tougher than carbon steel, such that more power and rigidity are needed in tooling. Second, the powerful work-hardening effect gives the austenitic grades the property of being instantaneously strengthened upon the first touch of the tool or pass of the roll. Machine tools must therefore bite surely and securely, with care taken not to “ride” the piece. Difficult forming operations warrant careful attention

S

to variations in grade that are available, also in heat treatment, for accomplishing end purposes without unnecessary work problems.

Finishing

These operations produce their best effects with stainless steels. No metal takes a more beautiful polish, and none holds it so long or so well. Stainlessness is not just skin-deep, but body through. And, of course, coatings are rendered entirely unnecessary.

Stainless Steel (Cast)

Cast stainless steels are divided into two classes: those intended primarily for uses requiring corrosion resistance and those intended mainly for uses requiring heat resistance. Both types are commonly known by the designations of the Alloy Casting Institute of the Steel Founders Society of America, and these designations generally begin with the letter C for those used mainly for corrosion resistance and with the letter H for those used primarily for heat resistance. All are basically iron–chromium or iron–chromium–nickel alloys, although they may also contain several other alloying ingredients, notably molybdenum in the heat-resistant type, and molybdenum, copper, and/or other elements in the corrosion-resistant type. The corrosion-resistant cast stainless steel type follows the general metallurgical classifications of the wrought stainless steels, that is, austenitic, ferritic, austenitic–ferritic, martensitic, and precipitation hardening. Specific alloys within each of these classifications are austenitic (CH-20, CK-20, CN-7M), ferritic (CB-30 and CC-50), austenitic–ferritic (CE-30, CF-3, CF-3A, CF-8, CF-8A, CF-20, CF-3M, CF-3MA, CF-8M, CF-8C, CF-16F, and CG-8M), martensitic (CA-15, CA-40, CA-15M, and CA-6NM), and precipitation hardening (CB-7Cu and CD-4MCu). The chromium content of these alloys may be as little as 11% or as much as 30%, depending on the alloy. The heat-resistant cast stainless steel types may contain as little as 9% chromium (Alloy HA), although most contain much greater amounts, such as 32% in HL. Although nickel content rarely exceeds chromium content in the corrosion-resistant type, it does in several heat-resistant types (HN, HP, HU, HW, and HX). In fact, nickel is the major ingredient in HU, HW, and HX. Several of the heat-resistant types can be used at temperatures as high as 1149°C. C-series grades are used in valves, pumps, and fittings. H-series grades are used for furnace parts and turbine components.

Applications

Iron–chromium alloys containing from 11.5% to 30% chromium and iron–chromium–nickel alloys containing up to 30% chromium and 31% nickel are widely used in the cast form for industrial process equipment at temperatures from –257°C to 649°C. The largest area of use is in the temperature range from room temperature to the boiling points of the materials handled.

Typical stainless castings are pumps, valves, fittings, mixers, and similar equipment. Chemical industries employ them to resist nitric, sulfuric, phosphoric, and most organic acids, as well as many neutral and alkaline salt solutions. The pulp and paper industry is a large user of high alloy castings in digesters, filters, pumps, and other equipment for the manufacture of pulp. Fatty acids and other chemicals involved in soap-making processes are often handled by high alloy casting. Bleaching and dyeing operations in the textile industry require parts made from high alloys. These corrosion-resistant alloys are also widely used in making synthetic textile fibers. Pumps and

valves cast of various high alloy compositions find wide application in petroleum refining. Other fields of application are food and beverage processing and handling, plastics manufacturer, preparation of pharmaceuticals, atomic-energy processes, and explosives manufacture. Increasing use is being made of cast stainless alloys for handling liquid gases at cryogenic temperatures.

Stainless Steel (Wrought)

Except for the precipitation-hardening (PH) stainless steels, wrought stainless steels are commonly designated by a three-digit numbering system of the American Iron and Steel Institute. Wrought austenitic stainless steels constitute the 2XX and 3XX series and the wrought ferritic stainless steels are part of the 4XX series. Wrought martensitic stainless steels belong either in the 4XX or 5XX series. Suffix letters, such as I, for low carbon content or Se for selenium, are used to denote special compositional modifications. Cast stainless steels are commonly known by the designations of the Alloy Casting Institute of the Steel Founders Society of America, which begin with letters CA through CN and are followed by numbers or numbers and letters. Powder compositions are usually identified by the designations of the Metal Powder Industries Federation.

Of the austenitic, ferritic, and martensitic families of wrought stainless steels, each as a general-purpose alloy. All of the others in the family are derivatives of the basic alloy, with compositions tailored for special properties. The stainless steel 3XX series has the largest number of alloys and stainless steel 302, a stainless “18-8” alloy, is a general-purpose one. Besides its 17%–19% chromium and 8%–10% nickel, it contains a maximum of 0.15% carbon, 2% manganese, 1% silicon, 0.4% phosphorus, and 0.03% sulfur. 302B is similar except for greater silicon (2%–3%) to increase resistance to scaling. Stainless steels 303 and 303Se are also similar except for greater sulfur (0.15% minimum) and, optionally, 0.6% molybdenum and 303, and 0.06 maximum sulfur and 0.15 minimum selenium in 303Se. Both are more readily machinable than 302. 304 and 304L stainless steels are low-carbon (0.08% and 0.03% maximum, respectively) alternatives, intended to restrict carbide precipitation during welding and, thus, are preferred to 302 for applications requiring welding. They may also contain slightly more chromium and nickel. 304N is similar to 304 except for 0.10%–0.16% nitrogen. The nitrogen provides greater strength than 302 at just a small sacrifice in ductility and a minimal effect on corrosion resistance. 305 has 0.12% maximum carbon but greater nickel (10.5%–13%) to reduce the rate of work hardening for applications requiring severe forming operations. S30430, as designated by the Unified Numbering System, contains 0.08 maximum carbon, 17%–19% chromium, 8%–10% nickel, and 3%–4% copper. It features a still lower rate of work hardening and is used for severe cold-heading operations. 308 contains more chromium (19%–21%) and nickel (10%–12%) and, thus, is somewhat more corrosion and heat resistant. Although used for furnace parts and oil-refinery equipment, its principal uses for welding rods because its higher alloy content compensates for alloy content that may be reduced during welding.

Stainless steels 309, 309S, 310, 310S, and 314 have still greater chromium and nickel contents. 309S and 310S are low-carbon (0.08% maximum) versions of 309 and 310 for applications requiring welding. They are also noted for high creep strength. Stainless steel 314, which like 309 and 310 contains 0.25% maximum carbon, also has greater silicon (1.5 to 3%), thus providing greater oxidation resistance. Because of the high silicon content, however, it is prone to embrittlement during prolonged exposure at temperatures of 649°C–816°C. This embrittlement, however, is only evident at room temperature and is not considered harmful unless the alloy is subject

to shock loads. These alloys are widely used for heaters and heat exchangers, radiant tubes, and chemical and oil-refinery equipment.

Stainless steels 316, 316L, 316F, 316N, 317, 317L, 321, and 329 are characterized by the addition of molybdenum, molybdenum and nitrogen (316N), or titanium (321). Stainless steel 360, with a 16%–18% chromium, 10%–14% nickel, and 2%–3% molybdenum, is more corrosion and creep resistant than 302- or 304-type alloys. Type 316L is the low-carbon version for welding applications; 316F, because of its greater phosphorus and sulfur, is the “free-machining” version; and 316N contains a small amount of nitrogen for greater strength. Stainless steels 317 and 317L are slightly richer in chromium, nickel, and molybdenum and, thus, somewhat more corrosion and heat resistant. Like 360, they are used for processing equipment in the oil, chemical, food, paper, and pharmaceutical industries. Type 321 is titanium-stabilized to inhibit carbide precipitation and provide greater resistance to intergranular corrosion in welds. Type 329, a high-chromium (25%–30%) low-nickel (3%–6%) alloy with 1%–2% molybdenum, is similar to 316 in general corrosion but more resistant to stress corrosion. Stainless steel 330, a high-nickel (34%–37%), normal chromium (17%–20%), 0.75%–1.5% silicon, molybdenum-free alloy, combines good resistance to carburization, heat, and thermal shock.

Stainless steels 347 and 348 are similar to 321 except for the use of columbium and tantalum instead of titanium for stabilization. Type 348 also contains a small amount (0.2%) of copper. Both have greater creep strength than 321 and they are used for welded components, radiant tubes, aircraft-engine exhaust manifolds, pressure vessels, and oil-refinery equipment. Stainless steel 384, with nominally 16% chromium and 18% nickel, is another low-work-hardening alloy used for severe cold-heading applications.

The stainless steel 2XX series of austenitics comprises 201, 202, and 205. They are normally chromium content (16%–19%), but low in nickel (1%–6%), high in manganese (5.5%–15.5%), and with 0.12%–0.25% carbon and some nitrogen. Types 201 and 202 have been called the low-nickel equivalents of 301 and 302, respectively. Type 202, with 17%–19% chromium, 7.5%–10% manganese, 4%–6% nickel, and a maximum of 1% silicon, 0.25% nitrogen, 0.15% carbon, 0.06% phosphorus, and 0.03% sulfur, is a general-purpose alloy. Type 201, which contains less nickel (3.5%–5.5%) and manganese (5.5%–7.5%), was prominent during the Korean War due to a nickel shortage. Type 205 has the least nickel (1%–1.75%), and the most manganese (14%–15.5%), carbon (0.12%–0.25%), and nitrogen (0.32%–0.40%) contents. It is said to be the low-nickel equivalent of 305 and has a low rate of work hardening that is useful for parts requiring severe forming operations.

Like stainless steels in general, austenitic stainless steels have a density of 7750–8027 kg/m³. Unlike some other stainless steels, they are essentially nonmagnetic, although most alloys will become slightly magnetic with cold work. Their melting range is 1371°C–1454°C, specific heat at 0°C–100°C is about 502 J/kg K, and electrical resistivity at room temperature ranges from 69×10^{-8} to 78×10^{-8} Ω m.

Types 309 and 310 have the highest resistivity, and 201 and 202 the lowest.

Most are available in many mill forms and are quite ductile in the annealed condition, tensile elongation's ranging from 35% to 70%, depending on the alloy. Although most cannot be strengthened by heat treatment, they can be strengthened appreciably by cold work. In the annealed condition, the tensile yield strength of all the austenitics falls in the range of 207–552 MPa, with ultimate strengths in the range of 517–827 MPa. But cold-working 201 or 301 sheet just to the half-hard temper increases yield strength to 758 MPa and ultimate strength to at least 1034 MPa. Tensile modulus is typically 193×10^3

to 199×10^3 MPa and decreases slightly with severe cold work. As to high-temperature strength, even in the annealed condition most alloys have tensile yield strengths of at least 83 MPa at 815°C, and some (308, 310) about 138 MPa. Types 310 and 347 have the highest creep strength, or stress-rupture strength, at 538°C–649°C. Annealing temperatures range from 954°C to 1149°C, initial-forging temperatures range from 1093°C to 1260°C, and their machinability index is typically 50 to 55, 65 for 303 and 303Se, relative to 100 for 1112 steel.

Among the many specialty wrought austenitic stainless steels are a number of nitrogen-strengthened stainless steels; Nitronic 20, 32, 33, 40, 50, and 60; 18–18 Plus and Marinaloy HN and 22; and SAF 2205 and 253MA. Nitrogen, unlike carbon, has the advantage of increasing strength without markedly reducing ductility. Some of these alloys are twice as strong as the standard austenitics and also provide better resistance to certain environments. All are normal or higher than normal in chromium content. Some are also normal or higher than normal in nickel content, whereas others are low in nickel and, in the case of 18-18 Plus, nickel-free. Nitronic 20, a 23% chromium, 8% nickel, 2.5% manganese alloy, combines high resistance to oxidation and sulfidation and was developed for engine exhaust valves. Unlike austenitics in general, it is hardenable by heat treatment. Solution treating at 1177°C, water quenching, and aging at 760°C provide tensile strengths of 579 MPa yield and 979 MPa ultimate. SAF 2205, and extra-low-carbon (0.03%), 22% chromium, 5.5% nickel, 3% molybdenum alloy, is a ferritic-austenitic alloy with high resistance to chloride- and hydrogen-sulfide-induced stress corrosion, pitting in chloride environments, and intergranular corrosion in welded applications.

The wrought ferritic stainless steels are magnetic and less ductile than the austenitics. Although some can be hardened slightly by heat treatment, they are generally not hardenable by heat treatment. All contain at least 10.5% chromium and, although the standard alloys are nickel-free, small amounts of nickel are common in the nonstandard ones. Among the standard alloys, stainless steel 430 is the general-purpose alloy. It contains 16%–18% chromium and a maximum of 0.12% carbon, 1% manganese, 1% silicon, 0.04% phosphorus, and 0.03% sulfur. Stainless steel 430F and 430FSe, the “free-machining” versions, contain more phosphorus (0.06% maximum) and sulfur (0.15% minimum in 430F, 0.06 maximum in 430FSe). 430FSe also contains 0.15% minimum selenium, and 0.6% molybdenum is an option for 430F. The other standard ferritics are stainless steels 405, 409, 429, 434, 436, 442, and 446. 405 and 409 are the lowest in carbon (0.08% maximum) and chromium (11.5%–14.5% and 10.5%–11.75%, respectively), the former containing 0.10%–0.30% aluminum to prevent hardening on cooling from elevated temperatures, and the latter containing 0.75% maximum titanium. Type 429 is identical to 430 except for less chromium (14%–16%) for better weldability. Types 434 and 436 are identical to 430 except for 0.75%–1.25% molybdenum in the former in this amount of molybdenum plus 0.70% maximum columbium and tantalum in the latter; these additives improve corrosion resistance in specific environments. Types 442 to 446 are the highest in chromium (18%–23% and 23%–27%, respectively) for superior corrosion and oxidation resistance, and in carbon (0.20% maximum). Type 446 also contains more silicon (1.50% maximum).

The standard alloys melt in the range of 1427°C–1532°C, thermal conductivities of 21–27 W/m K at 100°C, and electrical resistivities of 59–67 μΩ cm at 21°C. In the annealed condition, tensile yield strengths range from 241 to 276 MPa for 405 to as high as 414 MPa for 434, with ultimate strengths of 448–586 MPa and elongations of 20%–33%. For 1% creep in 10,000 h at 538°C, 430 has a stress-rupture strength of 59 MPa. Typical applications include automotive

S

trim and exhaust components, chemical-processing equipment, furnace hardware and heat-treating fixtures, turbine blades, and molds for glass.

Wrought martensitic stainless steels are also magnetic and, as they are hardenable by heat treatment, provide high strength. Of those in the stainless steel 4XX series, 410, which contains 11.5%–13.0% chromium, is the general-purpose alloy. The others, 403, 414, 416, 416Se, 420, 420F, 422, 431, 440A, and 440C, have similar (403, 414) or more chromium (16%–18% in the 440s). Most are nickel-free or, as in the case of 414, 422, and 431, low in nickel. Most of the alloys also contain molybdenum, usually less than 1%, plus the usual 1% or so maximum of manganese and silicon. Carbon content ranges from 0.15% maximum in 403 through 416 and 416Se, to 0.60%–0.75% in 440A, and as much as 1.20% in 440C. Type 403 is the low-silicon (0.50% maximum) version of 410; 414 is a nickel (1.25%–2.50%)-modified version for better corrosion resistance. Types 416 and 416Se, which contain 12%–14% chromium, also contain more than the usual sulfur or sulfur, phosphorus, and selenium to enhance machinability. Type 420 is richer in carbon for greater strength, and 420F has more sulfur and phosphorus for better machinability. Type 422, which contains the greatest variety of alloying elements, has 0.22%–0.25% carbon, 11%–13% chromium, low silicon (0.75% maximum), low phosphorus, and sulfur (0.025% maximum), 0.5%–1.0% nickel, 0.75%–1.25% of both molybdenum and tungsten, and 0.15%–0.3% vanadium. This composition is intended to maximize toughness and strength at temperatures to 649°C. Type 431 is a higher-chromium (15%–17%) nickel (1.25%–2.50%) alloy for better corrosion resistance. The high-carbon, high-chromium 440 alloys combine considerable corrosion resistance with maximum hardness. The stainless steel 5XX series of wrought martensitic alloys—501, 501A, 501B, 502, 503, and 504—contain less chromium, ranging from 4% to 6% in 501 and 502, to 8%–10% in 501 B and 504. All contain some molybdenum, usually less than 1%, and are nickel-free.

Most of the 4XX alloys can provide yield strengths greater than 1034 MPa and some, such as the 440s, more than 1724 MPa. The martensitic stainless steels, however, are less machinable than the austenitic and ferritic alloys and they are also less weldable. Forging temperatures range from 1038°C to 1232°C. Most of the alloys are available in a wide range of mill forms and typical applications include turbine blades, springs, knife blades and cutlery, instruments, ball bearings, valves and pump parts, and heat exchangers.

The wrought PH stainless steels are also called age-hardenable stainless steels. Three basic types are now available: austenitic, semi-austenitic, and martensitic. Regardless of the type, the final hardening mechanism is precipitation hardening, brought about by small amounts of one or more alloying elements, such as aluminum, titanium, copper, and, sometimes, molybdenum. Their principal advantages are high strength, toughness, corrosion resistance, and relatively simple heat treatment.

Of the austenitic PH stainless steels, A-286 is the principal alloying. Also referred to as an iron-based superalloys, it contains about 15% chromium, 25% nickel, 2% titanium, 1.5% manganese, 1.3% molybdenum, 0.3% vanadium, 0.15% aluminum, 0.05% carbon, and 0.005% boron. It is widely used for aircraft turbine parts and high-strength fasteners. Heat treatment solution treating at 981°C, water or oil quenching, aging at 718°C–732°C for 16 to 18 h and air cooling provides an ultimate tensile strength of about 1035 MPa and a tensile yield strength of about 690 MPa, with 25% elongation and a Charpy impact strength of 87 J. The alloy retains considerable strength at high temperatures. At 649°C, for example, tensile yield strength is 607 MPa. The alloy also has good weldability and its corrosion resistance in most environments is similar to that of 3XX stainless steels.

The semiaustenitic PH stainless steels are austenitic in the annealed or solution-treated condition and can be transformed to a martensitic structure by relatively simple thermal or thermomechanical treatments. They are available in all mill forms, although sheet and strip are the most common. True semi-austenitic PH 14-8 Mo, PH 15-7 Mo, and 17-7PH, AM-350 and AM-355 are also so classified, although they are said not truly to have a precipitation-hardening reaction. The above steels are lowest in carbon content (0.04% nominally in PH 14-8 Mo, 0.07% in the others). PH 14-8 Mo also nominally contains 15.1% chromium, 8.2% nickel, 2.2% molybdenum, 1.2% aluminum, 0.02% manganese, 0.02% silicon, and 0.005% nitrogen. PH 15-7 Mo contains 15.2% chromium, 7.1% nickel, 2.2% molybdenum, 1.2% aluminum, 0.50% manganese, 0.30% silicon, and 0.04% nitrogen. 17-7PH is similar to PH 15-7 Mo except for 17% chromium and being molybdenum-free. AM-350 contains 16.5% chromium, 4.25% nickel, 2.75% molybdenum, 0.75% manganese, 0.35% silicon, 0.10% nitrogen, and 0.10% carbon. AM-355 has 15.5% chromium, 4.25% nickel, 2.75% molybdenum, 0.85% manganese, 0.35% silicon, 0.12% nitrogen, and 0.13% carbon. In the solution-heat-treated condition in which these steels are supplied, they are readily deformable. They then can be strengthened to various strength levels by conditioning the austenite, transformation to martensite, and precipitation hardening. One such procedure, for 17-7PH, involves heating at 760°C, air cooling to 16°C, then heating to 565°C and air-cooling to room temperature. In their heat-treated conditions, these steels encompass tensile yield strengths ranging from about 1241 MPa for AM-355 to 1793 MPa for PH 15-7 Mo.

After solution treatment, the martensitic PH stainless steels always have a martensitic structure at room temperature. The steels include the progenitor of the PH stainless steels, Stainless W, PH 13-8 Mo, 15-5PH, 17-4PH, and Custom 455. Of these, PH 13-8 Mo and Custom 455, which contain 11%–13% chromium and about 8% nickel plus small amounts of other alloying elements, are the higher-strength alloys, providing tensile yield strengths of 1448 and 1620 MPa, respectively, in bar form after heat treatment. The other alloys range from 15% to 17% chromium and 4% to 6% nickel, and typically have tensile yield strengths of 1207–1276 MPa in heat-treated bar form. They are used mainly in bar form and forgings, and only to a small extent in sheet. Age hardening, following high-temperature solution treating, is performed at 427°C–677°C.

Stainless Steel Products

Metal fibers are used for weaving into fabrics for arctic heating clothing, heated draperies, chemical-resistant fabrics, and reinforcement in plastics and metals. Stainless-steel yarn made from the fibers is woven into stainless-steel fabric that has good creep resistance and retains its physical properties to 427°C. The fiber may be blended with cotton or wool for static control, particularly for carpeting.

Stainless (Steel/Iron)

Any iron or steel containing more than about 12% chromium can be termed stainless. With about 12% or more of chromium the material, when exposed to the normal atmosphere, rapidly forms a thin, impervious, chromium rich, oxide film which protects the underlying steel from further attack. There are many forms of stainless steel, see *steel*. The term Stainless Iron has also been used for many widely differing alloys ranging from 12% chromium low carbon steel to 30% chromium, high carbon cast-iron. It should be viewed with caution. See *steel* for further commentary on stainless steels.

Staking

Fastening two parts together permanently by recessing one part within the other and then causing plastic flow at the joint.

Stalagmometer

An apparatus for determining surface tension. The mass of a drop of liquid is measured by weighing a known number of drops or by counting the number of drops obtained from a given volume of the liquid.

Stamping

The general term used to denote all sheet metal pressworking. It includes blanking, shearing, hot or cold forming, drawing, bending, and coining. (1) Pressing and forging sheet and plate in closed dies.

Stand

(1) A piece of rolling mill equipment containing one set of work rolls. In the usual sense, any pass of a cold-or hot-rolling mill. (2) Two or more rolls in a housing. See *rolling mill*.

Standard

(1) A basis of comparison on which units are based. For example, units of measurement were traditionally based on a solid metal standard bar retained by some national or international body. (2) A specification covering all relevant aspects of a material, procedure, system, etc. Aspects defined include composition, properties, dimensions and performance.

Standard Addition

In chemical analysis, a method in which small increments of a substance under measurement are added to a sample under test to establish a response function or, by extrapolation, to determine the amount of a constituent originally present in the sample.

Standard Deviation

A measure of the dispersion of observed values or results from the average expressed as the positive square root of the variance.

Standard Electrode Potential

The reversible potential for an electrode process when all products and reactions are at unit activity on a scale in which the potential for the standard hydrogen half-cell is zero.

Standard Gold

(1) A gold alloy containing 10% copper; at one time used for legal coinage in the United States. (2) In the United Kingdom, 91.66% gold, remainder copper.

Standard Grain-Size Micrograph

A micrograph of a known grain size at a known magnification that is used to determine grain size of metals by direct comparison with another micrograph or with the image of a specimen.

Standardization

(1) The process of establishing, by common agreement, engineering criteria, terms, principles, practices, materials, items, processes, and equipment parts and components. (2) The adoption of generally accepted uniform procedures, dimensions, materials, or parts that directly affect the design of a product or a facility. (3) In analytical chemistry, the assignment of a compositional value to one standard on the basis of another standard.

Standard Reference Material

A reference material, the composition or properties of which are certified by a recognized standardizing agency or group.

Standard Silver

In the United Kingdom, 92.5% silver, remainder copper. In the United States, 90% gold, remainder copper.

Standard Wire Gauge

A series of standard diameters.

Standoff Distance

The distance between a nozzle on a welding or cutting torch and the base metal.

Staple Fibers

Fibers for reinforcing plastics that are of spinnable length manufactured directly or by cutting continuous filaments to short lengths (usually 13–50 mm, or 1/2–2 in., long, and 1–5 denier). See also *denier*.

Starch

A large group of natural carbohydrate compounds occurring in grains, tubers, and fruits. The common cereal grains contain 55% to 75% starch, and potatoes contain about 18%. Starches have a wide usage for foodstuffs, adhesives, textile and paper sizing, gelling agents, and fillers; in making explosives and many chemicals; and for making biodegradable detergents such as sodium tripolyphosphate. Starch is a basic need of all peoples and all industries. Much of it is employed in its natural form, but it is also easily converted to other forms, and more than 1000 different varieties of starch are usually on the U.S. market at any one time.

Most of the commercial starch comes from corn, potatoes, and mandioca. Starches from different plants have similar chemical reactions, but all have different granular structure, and the differences in size and shape of the grains have much to do with the physical properties. **Cornstarch** has a polygonal grain of simple structure. It is the chief food starch in the western world, although sweet-potato starch is used where high gelatinization is desired, and tapioca starch is used to give quick tack and high adhesion in glues. **Tapioca starch** has rounded grains truncated on one side and is of lamellar structure. It produces gels of clarity and flexibility, and because it has no serial flavor, it can be used directly for thickening foodstuffs. **Rice starch** is polygonal and lamellar, and has very small particles. It makes an opaque stiff gel and is also valued as a dusting starch for bakery products, although it is expensive for this purpose.

S

White-potato starch has conchoidal or ellipsoidal grains of lamellar structure. When cooked, it forms clear solutions easily controlled in viscosity, and gives tough, resilient films for coating paper and fabrics. Prolong grinding of grain starches reduces the molecular chain, and the lower weight then gives greater solubility in cold water. Green fruits, especially bananas often contain much starch, but the ripening process changes the starch to sugars.

In general, starch is a white, amorphous powder having a specific gravity from 0.499 to 0.513. It is insoluble in cold water but can be converted to **soluble starch** by treating with a dilute acid. When cooked in water, starch produces an adhesive paste. Starch is easily distinguished from dextrans as it gives a blue-color with iodine while dextrans give violet and red. The starch molecule is often described as a chain of glucose units, with the adhesive **waxy starches** as those with coiled chains. But starch is a complex member of the great group of natural plant compounds consisting of starches, sugars, and cellulose, and originally named carbohydrates because the molecular formula could be written as $C_n(H_2O)_n$; but not all now-known carbohydrates can be classified in this form, and many now-known acids and aldehydes can be indicated by this formula.

Star Craze

Multiple fine surface separation cracks in protruded reinforced plastics that appear to emanate from a central point in that exceed 6 mm (1/4 in.) in length, but do not penetrate deep equivalent depth of a full ply of reinforcement. This condition is often caused by impact damage. See also *crazing* (plastics).

Stardusting

An extremely fine form of roughness on the surface of a metal deposit.

Stark Effect

A shift in the energy of spectral lines due to an electrical field that is either externally applied or is an internal field caused by the presence of neighboring ions or atoms in a gas, solid, or liquid.

Starting Sheet

A thin sheet of metal used as the cathode in electrolyte refining.

Starting Torque

The torque that is required for initiating rotary motion.

Starved Area

An area in a reinforced plastic part that has an insufficient amount of resin to wet out the reinforcement completely. This condition may be due to improper wetting, impregnation, or resin flow; excessive molding pressure; or incorrect bleeder cloth thickness.

Starved Joint

An adhesive bonded joint that has an insufficient amount of adhesive to produce a satisfactory bond. This condition may result from

too thin a spread to fill the gap between the adherends, excessive penetration of the adhesive into the adherend, too short an assembly time, or the use of excessive pressure.

State of Strain

A complete description of the deformation within a homogeneous deformed volume or at a point. The description requires, in general, the knowledge of the independent components of *strain*.

State of Stress

A complete description of the stresses within a homogeneously stressed volume or at a point. The description requires, in general, the knowledge of the independent components of *stress*.

Static

Stationary or very slow. Frequently used in connection with routine testing of metal specimens. Contrast with *dynamic*.

Static Coefficient of Friction

The *coefficient of friction* corresponding to the maximum friction force that must be overcome to initiate macroscopic motion between two bodies.

Static Electrode Force

The force between the electrodes in making spot, seam, or projection welds by resistance welding under welding conditions, but with no current flowing and no movement in the welding machine.

Static Equivalent Load ($P_{0 \text{ metal}}$)

In rolling-element bearings, the static load which, if applied, would give the same life as that which the bearing will attain under actual conditions of load and rotation. See also *rating life*.

Static Fatigue

A term sometimes used to identify a form of hydrogen embrittlement in which a metal appears to fracture spontaneously under a steady stress less than the yield stress. There almost always is a delay between the application of stress (or exposure of the stressed metal to hydrogen) and the onset of cracking. More properly referred to as *hydrogen-induced delayed cracking*. Contrast with *fatigue*.

Static Friction

See *limiting static friction*.

Static Hot Pressing

A method of applying a static load uniaxially during hot pressing of metal or ceramic powders. Contrast with *dynamic hot pressing* and *isostatic hot pressing*. See also *hot pressing*.

Static Load Rating (C_0)

In rolling-element bearings, the static load that corresponds to a permanent deformation of rolling element and race at the most heavily stressed contact of 0.00001 of the rolling-element diameter. See also *rating life*.

Static Modulus

The ratio of stress to strain under static conditions. It is calculated from static stress-strength tests, in shear, compression, or tension. Expressed in force per unit of area.

Static Plate

See *explosive welding*.

Static Stress

A stress in which the force is constant or slowly increasing with time, for example, test to failure without shock.

Static Viscosity

See *viscosity*.

Stationary Phase

In chromatography, a particulate material packed into the column or a coating on the inner walls of the column. A sample compound in the stationary phase is separated from compounds moving through the column as a result of being in the mobile phase. See also *mobile phase*.

Statistic

A summary value calculated from the observed values in a sample.

Statistical Process Control

The application of statistical techniques for measuring and analyzing the variation in processes.

Statistical Quality Control

The application of statistical techniques for measuring and improving the quality of processes and products (includes statistical process control, diagnostic tools, sampling plans, and other statistical techniques).

Statuary Bronze

Copper alloys used for casting statues, plaques, and ornamental objects that require fine detail and a smooth, reddish surface. Most of the famous large bronze statues of Europe contain 87% to 90% copper, with varying amounts of tin, zinc, and lead. Early Greek statues contain 9% to 11% tin with as much as 5% lead added apparently to give greater fluidity for crisp details. A general average bronze will contain 90% copper, 6% tin, 3% zinc, and 1% lead. Statuary bronze for cast plaques used in building construction contains 86% copper, 2% tin, 2% lead, 8% zinc, and 2% nickel. The nickel improves fluidity and hardness and strengthens the alloy, and the lead promotes an oxidized finish on exposure. The statuary bronze used for hardware has 83.5% copper, 4% lead, 2% tin, and 10% zinc.

Staving

A tube manipulation process for increasing the external diameter and maintaining the bore constant. Also termed *upsetting*.

Stave Bearing

A *sleeve bearing* consisting of several axially held slats or staves on the outer surface of which the bearing material is bonded.

Stay

A structural member of slender proportions, such as a bar, beam or wire, carry tensile loads.

Steadite

(1) A hard structural constituent of cast iron that consists of a binary eutectic of ferrite, containing some phosphorus in solution, and iron phosphide (Fe_3P). The eutectic consists of 10.2% P and 89.8% Fe. The melting temperature is 1050°C. (2) The eutectic between austenite and iron phosphide in cast iron.

Stead's Brittleness

A condition of brittleness that causes transcrystalline fracture in the coarse grain structure that results from prolonged annealing of thin sheets of low-carbon steel previously rolled at a temperature below about 705°C. The fracture usually occurs at about 45°C to the direction of rolling.

Steady Load

Loads that do not change in intensity, or change so slowly that they may be regarded as steady.

Steady-Rate Creep

See *creep*.

Steadyrest

In cutting or grinding, a stationary support for a long workpiece.

Steam Blanketing

Power plant boilers generate steam by circulating water through tubes fired, i.e., heated, on their exterior. Normally, the steam is generated as discrete bubbles termed (*nucleate boiling*) which rise by gravity or are swept by the pump circulation. However, where the heat flux is excessive steam can form a persistent layer along the bore towards the fire. This layer is termed a *steam blanket* and can lead to various adverse effects, including caustic attack, excessive thickness and fissuring of the normally protective magnetite film, overheating of the tube and distortion.

Steam Erosion

Erosion of high velocity steam impinging on a component. In practice, erosion by pure gaseous steam is rare and the term is often a misnomer (although see wire drawing). Usually, the damage is

S

caused either by entrained solids, see *solid particle erosion* or by water droplets. The term is commonly used regarding the damage observed on the last stage of moving blades of a steam turbine where the steam is very “wet” containing a considerable amount of condensed water droplets. However, even in this case the steam velocity is not responsible for the metal loss since the damaging droplets are those that drip off the stationary blades to be impacted by the moving blades. Once droplets have been accelerated to steam velocity they follow the streamline flow and cause little damage. Strictly, also, this form of water droplet damage is not a form of abrasion by a cutting action, rather it is the result of repeated high velocity impact and hence is more akin to a surface fatigue process. The surface produced is not smooth or grooved but develops a “Cats Tongue” texture of sloping sharp spikes and pits which become progressively coarser as damage progresses.

Steam Hammer

A type of *drop hammer* in which the ram is raised for each stroke by a double-action steam cylinder and the energy delivered to the workpiece is supplied by the velocity and weight of the ram and attached upper die driven downward by steam pressure. The energy delivered during each stroke can be varied.

Steam Molding

A process used to mold plastic parts from pre expanded beads of polystyrene using steam as a source of heat to expand the blowing agent in the material. The steam in most cases is in direct, intimate contact with the beads. It may also be used indirectly, by heating mold surfaces that are in contact with the bead.

Steam Side

See *fire side*.

Steam Treatment

The treatment of a sintered ferrous part in steam at temperatures between 510°C and 595°C in order to produce a layer of black iron oxide (magnetite, or ferrous-ceric oxide, $\text{FeO-Fe}_2\text{O}_3$) on the exposed surface for the purpose of increasing hardness and wear resistance.

Steatite

A compact, massive rock composed principally of *tal*c (magnesium silicate). Ground steatite is used in *porcelain enamels* and *ceramic whiteware*. See *soapstone*.

Steckel Mill

A cold reducing mill having two working rolls and two backup rolls, none of which is driven. The strip is drawn through the mill by a power reel in one direction as far as the strip will allow and then reversed by a second power reel, and so on until the desired thickness is attained.

Steel

Steel is iron alloyed with small amounts of carbon, 2.5% maximum, but usually much less. The two broad categories are carbon steels

and alloy steels, but they are further classified in terms of composition, deoxidation method, mill-finishing practice, product form, and principal characteristics. Carbon is the principal influencing element in carbon steels, although manganese, phosphorus, and sulfur are also present in small amounts, and these steels are further classified as low-carbon steels and sometimes referred to as mild steel (up to 0.30% carbon), medium-carbon steels (0.30%–0.60%), and high-carbon steels (more than 0.60%). The greater the amount of carbon, the greater the strength and hardness, and the less ductility. Alloy steels are further classified as low-alloy steels, alloy steels, and high-alloy steels; those having as much as 5% alloy content are the most widely used. The most common designation systems for carbon and alloy steels are those of the American Iron and Steel Institute and the Society of Automotive Engineers, which follow a four- or five-digit numbering system based on the key element or elements, with the last two digits indicating carbon content in hundredths of a percent.

Plain carbon steels (with 1% maximum manganese) are designated 10XX; resulfurized carbon steels, 11XX; resulfurized and rephosphorized carbon steels, 12XX; and plain carbon steels with 1%–1.65% manganese, 15XX. Alloy steels include manganese steels (13XX), nickel steels (23XX and 25XX), nickel-chromium steels (31XX–34XX), molybdenum steels (40XX and 44XX), chromium–molybdenum steels (41XX), nickel–chromium–molybdenum steels (43XX, 47XX, and 81XX–98XX), nickel–molybdenum steels (46XX and 48XX), chromium steels (50XX–52XX), chromium–vanadium steels (61XX), and tungsten–chromium steels (72XX), and silicon–manganese steels (92XX). The letter B following the first two digits designates boron steels and the letter L leaded steels. The suffix H is used to indicate steels produced to specific hardenability requirements. High-strength, low-alloy steels are commonly identified by a 9XX designation of the SAE, where the last two digits indicating minimum tensile yield strength in 1000 psi (6.8 MPa).

In contrast to rimmed steels, which are not deoxidized, killed steels are deoxidized by the addition of the oxidizing elements, such as aluminum or silicon, in the ladle prior to ingot casting, thus, such terms as aluminum-killed steel. Deoxidation markedly improves the uniformity of the chemical composition and resulting mechanical properties of mill products. Semikilled steels are only partially deoxidized, those intermediate in uniformity to rimmed and killed steels. Capped steels have a low-carbon steel rim characteristic of rimmed-steel ingot and central uniformity more characteristic of killed-steel ingot, and are well suited for cold-forming operations.

Steels are also classified as air-melted, vacuum-melted, or vacuum-degassed. Air-melted steels are produced by conventional melting methods, such as open hearth, basic oxygen, and electric furnace. Vacuum-melted steels are produced by induction vacuum melting and consumable electrode vacuum melting. Vacuum-degassed steels are air-melted steels that are vacuum processed before solidification. Vacuum processing reduces gas content, nonmetallic inclusions, and center porosity, and segregation. Such steels are more costly, but have better ductility and impact and fatigue strengths.

Steel-mill products are reduced from ingot into such forms as blooms, billets, and slabs, which are then reduced to finished or semifinished shape by hot-working operations. If the final product is produced by hot working, the steel was known as hot-rolled steel. If the final product is shaped cold, the steel was known as cold-finished steel or, more specifically, cold-rolled steel, or cold-drawn steel. Hot-rolled mill products are usually limited to low- and medium-nonheat-treated carbon steels. They are the most

economical steels, have good formability and weldability, and are widely used. Cold-finished steels, compared with hot-rolled products, have greater strength and hardness, better surface finish, and less ductility. Wrought steels are also classified in terms of mill-product form, such as bar steels, sheet steels, and plate steels. Cast steels refer to those used for castings, and P/M (powder metal) steels refer to powder compositions used for P/M parts. Steels are also known by their key characteristic from the standpoint of application, such as electrical steels, corrosion-resistant stainless steels, low-temperature steels, high-temperature steels, boiler steels, pressure-vessel steels, etc.

Steel Powder

Steel powder is used mainly for the production of steel powder metal parts made by consolidating the powder under pressure and then sintering, and, to a limited extent, for steel-mill products, principally tool-steel bar products. For powder metal parts, the powder may be admixed for the desired composition or prealloyed, that is, each powder particle is of the desired composition. For mill products, prealloyed powder is used primarily. Steel powder is widely used to make small- to moderate-size powder metal parts, with compositions closely matching those of wrought steels. Among the more common are carbon steels, copper steels, nickel steels, nickel-molybdenum steels, and stainless steels.

Steel Wool

Steel wool consists of long, fine fibers of steel used for abrading, chiefly for cleaning utensils and for polishing. It is made from low-carbon wire that has high tensile strength, usually having 0.10%–0.20% carbon and 0.50%–1% manganese. The wire is drawn over a track and shaved by stationary knife bearing down on it, and may be made in a continuous piece as long as 30,480 m. Steel wool usually has three edges but may have four or five, and strands of various types are mixed. There are nine standard grades of steel wool, the finest of which has no fibers greater than 0.0027 cm thick; the most commonly used grade has fibers that vary between 0.006 and 0.010 cm. Steel wool comes in batts, or in flat ribbon form on spools usually 10 cm wide. Stainless steel wool is also made, and copper wool is marketed for some cleaning operations.

Steel Types

Steel normally contain less than about 1.5% carbon and are categorized, rather imprecisely, on the basis of their carbon and alloy element content. Some of the more common terms are:

Plain carbon steels contain no significant quantity of alloying elements other than carbon and manganese and are subcategorized as follows:

Mild steel or, less commonly, low carbon steel, containing less than about 0.2% carbon. It has limited capability of hardened by heat treatment (as described below) and is usually used in the normalized or cold work condition.

Carbon steel containing more than about 0.25% carbon, often further subdivided into medium carbon steel containing 0.25% to about 0.5% carbon. High carbon steel containing 0.5% to about 1.2% or, rarely 2% carbon. Carbon manganese steel containing carbon in widely varying amounts plus manganese of about 1%–2%. Note that lesser amounts of manganese present in most steels do not merit this description.

Alloy steel has one or more elements, other than carbon and manganese below about 2%, deliberately added to approve some property. Such steels are often designated by their principal alloy content(s) e.g., “Nickel steel,” “Chrome (ium) Moly(bdenum) steel,” etc. Almost invariably, carbon is also present and unless the other alloying elements are present in large quantities, the steel responds to heat treatment broadly as summarized below. In a few specialized alloy steels, carbon may be deliberately excluded.

High alloy steel is another imprecise term but it usually implies a total alloy content above about 5%, excluding carbon and manganese.

Steel Physical Metallurgy and Heat Treatment

An important characteristic of iron is that it is a ferrite or alpha (α) phase, with a body centered cubic (BCC) crystal lattice structure. From 910°C to about 1400°C the stable phase is austenite or gamma (γ) with a face centered cubic (FCC) arrangement. Between 1400°C and a melting point at about 1530°C the structure returns to the BCC form but is referred to as delta (δ) phase or delta ferrite. Note, there is no beta phase in iron. It used to be thought that a beta phase existed between 910°C and the Curie point, that is the change from magnetic to nonmagnetic, at 770°C. In the case of pure iron, the change from one phase to another is not readily detectable outside the laboratory and has no great commercial significance. However, the addition of small amounts of carbon to form steel introduces a series of useful effects.

The solubility of carbon in iron varies considerably. In the low-temperature ferritic phase solubility is very low, about 0.03% maximum. However, the austenitic phase can hold in solid solution all of the carbon present in conventional steels. Furthermore, the addition of carbon extends the temperature range over which austenite can exist under equilibrium conditions. Thus, on slow cooling, the austenite does not transform fully to ferrite at 910°C which commences to transform in some lower temperature, termed the Upper Critical Temperature, which depends on the carbon content. Transformation then continues progressively as the temperature falls further but the ferrite which is formed contains very little carbon so the remaining austenite becomes progressively richer in carbon. Ultimately, at a specific temperature, all of the remaining carbon rich austenite will transform to a mixture of ferrite and iron carbide, Fe_3C also termed cementite. This temperature, 723°C in plain carbon steels, is termed the Eutectoid Temperature or the Lower Critical Temperature. The upper and lower critical temperatures are also referred to as, respectively, the A_3 and the A_1 . The term A_2 is rarely used but refers to the change at 770°C at which iron ceases to be magnetic. Often, the “A” temperatures are further defined as in A_{r1} or A_{c1} . The “r” suffix denotes the temperature measured during cooling (from the French *refroidissement*) and “c” the temperature measured during heating (*chauffage*). The range of temperature between A_1 and A_3 is variously described as the Critical Range, or Transition Range. The mixture of ferrite and cementite formed at 723°C is usually precipitated as the eutectoid form comprising alternate plates, or lamellae, of carbide and ferrite. This has an appearance under the microscope similar to mother of pearl, hence its name-pearlite. Microstructures formed in this way usually comprise grains of ferrite plus grades of pearlite, the amount of pearlite being roughly proportional to the quantity of carbon in the steel with about 0.8% carbon, termed the Eutectoid Composition, giving a fully pearlitic structure. The terms Hypo- and Hyper-eutectoid indicate, respectively, compositions of lower and higher carbon content. Hypereutectoid steels have a structure comprised predominantly of pearlite with a small amount of cementite as films or discrete areas. In isolation,

S

cementite is hard and brittle but pearlite, with its alternate layers of cementite and relatively soft, tough ferrite, provides a good combination of hardness, strength and toughness. Generalizing, the hardness of the steel increases with a proportion of pearlite in the microstructure.

All of the treatments considered so far have involved slow cooling rates so that appreciable diffusion can occur and transformation effectively reaches the stable equilibrium state. The process of very slow cooling from above the transition range, often in a furnace, is termed annealing or full annealing. This produces a coarse pearlite and ferrite structure with the steel in a soft, low strength, condition. A slightly faster cooling, which is usually achieved by removing the steel from the furnace to cool in still air, is termed normalizing. This produces a finer pearlite with slightly higher strength and hardness but for practical purposes normalized steel is still usually regarded as being in a softened condition and a near equilibrium state. However, if a steel is cooled more rapidly, by quenching, into oil, water or brine etc., insufficient time is available for diffusion. This forces transformation to take place below the A_1 resulting in nonequilibrium transformation. With only a slight increase in cooling rate the effect is to precipitate a finer form of pearlite but as the rate increases the lamellar form is suppressed and the carbide is deposited as a dispersion of particles in an acicular i.e., needlelike, ferrite matrix. This structure is called bainite. Depending upon the precise cooling rate, bainite can form over a wide range of temperature below about 550°C. Transformation high in this range produces upper bainite with a microscopical appearance often described as “feathery.” Faster cooling delays transformation to a lower temperature producing the more obviously acicular structure of lower bainite. Bainitic structures have a higher hardness than the ferritic/pearlitic structures.

At even higher cooling rates, i.e., when the Critical Cooling Rate is exceeded, Martensite is formed by a diffusionless shear process which commences at the M_s (martensite start) temperature and continues until the M_f (martensite finish) temperature. Transformation is not time-dependent but is a function of the temperature in the M_s – M_f range. In terms such as “ M_{10} temperature” the subscript indicates the percentage transformation to martensite at the temperature in question. If the M_f temperature is below ambient, the transformation to martensite will remain incomplete and the structure will contain retained austenite. This may be transformed to martensite by further cooling and the steel will remain fully martensitic on return to ambient. Fully martensitic structures offer the maximum hardness that can be developed by heat treatment of plain carbon steels.

The process of heating a steel into the austenitic range and then cooling at a rate sufficient to cause transformation to bainite or martensite is usually referred to as hardening. The martensitic structures in particular are hard and of high tensile strength but they tend to be brittle. Consequently, quenched steels are usually reheated for an hour or so to temperatures in the range 100°C–600°C to produce progressively softer, but more tough steels. This treatment, termed tempering, causes the metastable bainite and martensite phases to transform progressively to ferrite and iron carbide. The carbide particles produced by low temperature tempering are extremely fine and difficult to resolve in a light microscope but become increasingly coarse the higher the tempering temperature. Modern practices have referred to the structures as tempered martensites or tempered bainites. Earlier practice used the term troostite, defined as a dark etching, unresolvable structure developed by light tempering, i.e., up to about 300°C and sorbite defined as a fine, but resolvable, iron carbide in a ferrite matrix produced by tempering above about 400°C. When the tempering temperature exceeds about 500°C the

carbides become increasingly coarse and are usually described as spheroidized carbide although the terms sorbite or sorbitic carbide are still occasionally used. Cooling rate is not critical for tempering treatments but the time at temperature does affect the structure particularly at higher temperatures where longer times produce coarser carbides.

Up to this point interest has centered on plain carbon steels, that is ones that contain no deliberate alloying additions apart from carbon and up to about 2% manganese. The steels can develop very high strengths, but to do so, they need to be cooled very rapidly during the hardening process. This is readily achieved in the case of small components but with larger sizes the material, particularly at the center of this section, will not achieve the critical cooling rate to transform to martensite. A further problem associated with rapid cooling is that it can cause distortion or even cracking particularly of complex shaped items. This latter problem arises partly because of the thermal contraction that occurs as the temperature falls and partly because of the volume change associated with the various phase changes. These difficulties are overcome by adding to the steel further alloying elements that delay transformation so that slower cooling rates can develop the martensite or bainite structures. Many elements have this affect including manganese, nickel, chromium, molybdenum, vanadium and, of course increase carbon. They are said to confer hardenability. This term, therefore, refers to the ease with which a steel may be hardened; it does not refer to the level of hardness that can be achieved. Hardenability is measured in terms of the maximum section size, or ruling section, that can be fully hardened by a given cooling rate. Some of the elements that are added remain in solid solution but others can combine with the carbon to form alloy carbides which can confer further beneficial effects or, in other circumstances, present problems. When large amounts of some alloying elements, such as nickel and manganese, are added to the steel the transformation characteristics are changed to such an extent that the steel remains partially or fully austenitic down to ambient temperature even when slowly cooled. Such steels are termed austenitic steel, or, if they are partly austenitic, they may be termed duplex. Fully austenitic steels are nonmagnetic and, since they remain austenitic they cannot be hardened by rapid cooling. If, in addition to the austenite stabilizing elements (nickel and manganese), the steel contains more than about 12% chromium it can be termed austenitic stainless steel which is considered further below. It will be recognized, however, that not all austenitic steels are stainless.

Steels, Corrosion Resistant

An adverse characteristic of iron and steel that influences their usefulness is the lack of corrosion resistance. Iron reacts with oxygen in the atmosphere to form a range of iron oxides. The rate of attack is dramatically increased in the presence of moisture and the oxide formed in these circumstances is often combined with water to form rust. The unfortunate characteristics of rust are that it is very bulky compared with the iron that it replaces, it is readily detached and, most critically, it does not form a barrier to further contact with the environment. Consequently, rusting continues progressively in appropriate atmospheres until the iron is consumed. Most alloying elements have little effect on the corrosion resistance of iron. Elements such as copper, aluminum, and silicon can confer a small benefit in certain environments but only chromium has a major effect. Chromium reacts with atmospheric oxygen very strongly and rapidly but the oxide formed is thin, transparent, tightly adherent and acts as a barrier to further attack. This benefit is conferred on iron if the chromium content of the alloy exceeds about 12%. Thus, steels

with more than this quantity of chromium are referred to as stainless steels. If chromium is the only significant element the alloy is sometimes referred to as stainless iron but this term has been applied to various steels and cast irons and it should be used and interpreted with caution. The term ferritic stainless steel usually indicates an iron chromium alloy containing in sufficient carbon to undergo a hardening heat treatment as described above, while higher carbon alloys that can be hard and are termed martensitic stainless steel. If more than about 8% nickel is added to a high chromium steel the austenite to ferrite transformation is suppressed to such an extent that the material remains austenitic at normal ambient temperatures and the alloy is referred to as austenitic stainless steel. A common alloy contains 18% chromium plus 8% nickel,—hence the popular designation ‘18/8’ stainless. Stabilized stainless steels, contain elements, such as titanium and niobium, having a strong affinity for carbon which otherwise, in adverse circumstances could combine with some of the chromium at the grain boundaries with consequent susceptibility to intergranular corrosion. Austenitic steels cannot be hardened by conventional heat treatment as described above but certain more complex stainless steels can be hardened by precipitation hardening processes.

Steels-Alloy

So many specialized steels have been developed for particular applications that they cannot all be dealt with. However, some further limited information on a few of the more common special alloys is provided under headings such as Maraging, Silver and Tool Steels and on some specialized heat treatments under headings such as Austempering and Martempering.

Steels

For specific types, see *alloy steels*, *austenitic manganese steels*, *bearing steels*, *stainless steels*, *carbon steels*, *cast corrosion-resistant stainless steels*, *cast heat-resistant stainless steels*, *chromium-molybdenum heat-resistant steels*, *dual-phase steels*, *duplex stainless steels*, *high-strength low-alloy steels*, *low-alloy steels*, *stainless steels*, *tool steels*, and *ultrahigh-strength steels*.

Stellite

A range of proprietary alloys mostly based on cobalt and having excellent corrosion resistance, hardness and strength.

Step Aging

Aging of metals at two or more temperatures, by steps, without cooling to room temperature after each step. See also *aging*, and compare with *interrupted aging* and *progressive aging*.

Stepback Sequence

See preferred term *backstep sequence*.

Step Bearing

A plain surface bearing that supports the lower end of a vertical shaft. Other types of bearings may be thus described when they are mounted on a step or bracket. See also *Rayleigh step bearing* and *stepped bearing*.

Step Brazing

The brazing of successive joints on a given part with filler metals of successively lower brazing temperatures so as to accomplish the joining without disturbing the joint previously brazed. A similar result can be achieved at a single brazing temperature if the remelt temperature of prior joints is increased by metallurgical interaction.

Stepdown Test

A test involving the preparation of a series of machined steps progressing inward from the surface of a metal bar (usually steel) for the purpose of detecting by visual inspection the internal laminations caused by inclusion segregates.

Stepped Bearing

A thrust bearing in which the working face consists of one or more shallow steps. A distinction should be drawn between a stepped bearing and a *step bearing*.

Stepped Compact

A powder metallurgy compact with one (dual step) or more (multi-step) abrupt cross-sectional changes, usually obtained by pressing with split punches, each section of which uses a different pressure and a different rate of compaction. See also *split punch*.

Stepped Extrusion

See *extrusion*.

Step Fracture (Glass)

See *striation* (glass).

Step Fracture (Metals)

- (1) Cleavage fractures that initiate on many parallel cleavage planes.
- (2) Faceted cleavagelike fractures that occur during Stage I fatigue fractures (high-cycle, low-stress fractures).

Step Soldering

The soldering of successive joints on a given part with solders of successively lower soldering temperatures so as to accomplish the joining without disturbing the joints previously soldered.

Step (Fatigue) Test

A fatigue test program in which a specimen is subjected to a prescribed number of cycles at each of a series of progressively increasing stresses. The fatigue limit is then taken as the penultimate stress, i.e., the highest that did not cause failure or, alternatively, the average of the penultimate and the final stresses.

Stereo Angle

One half of the angle through which the specimen is tilted when taking a pair of *stereoscopic micrographs*. The axis of rotation lies in the plane of the specimen.

S

Stereographic Projection

A technique for presenting, in two dimensions, information on the three-dimensional orientation of crystallographic planes. The unit cell of a crystal comprises a small number of atoms arranged in a simple geometric pattern, for example, at the corners of a cube. The crystallographic planes are the planes on which the atoms lie, for example, the cube faces or the cube diagonals. The basic stereographic projection usually deals with a single crystal which, for the purpose of the exercise, is considered to be located at the center of a large sphere. For example, take the technique for a single plane, C. A line is projected perpendicularly from plane C to intersect the sphere surface at point P. A further line is then drawn from P to the pole of the other hemisphere, point S. The point D at which this line pierces the equatorial plane is the stereographic projection of the plane C. This procedure is repeated for all crystallographic planes of interest and the pattern of the series of D points forms the stereographic projection of the crystal. The technique can also be applied to multiple crystals such as a small piece of sheet. If the crystals of this sheet are aligned at random then the D points will be randomly distributed on the stereographic projection. However, a grouping of points will be evidence of preferred orientation. The term pole figure is often used interchangeably with the term stereographic projection. Where they are differentiated, pole figure usually refers to projections of multiple crystals.

Stereoisomer

An isomer in which atoms are linked in the same order but differ in their arrangement. See also *isomer* and *isotactic stereoisomerism*.

Stereolithography

Stereolithography uses a laser beam to convert a special photosensitive polymer from liquid to solid. The liquid polymer is held in a tank that also contains a platform that can be raised and lowered and onto which the part will be built.

The platform is first positioned just below the surface of the liquid polymer, and a laser beam is rastered across the surface of the polymer to solidify a two-dimensional image of the bottom layer of the part. The platform is then lowered a small distance to allow a thin layer of liquid polymer to cover the solidified layer, and the laser beam is again rastered to solidify the next layer on top of and bonded to the initial layer. The platform is lowered again to form the third layer, and so on.

When the final (top) layer of the part has been solidified, the platform is raised from the tank to drain away the liquid polymer from the finished part. Very complex shapes can be formed, including holes and even internal hollows (if a means is provided to drain out the unsolidified polymer).

Problems

Overhangs and undercuts are a challenge to form by stereolithography because the lower layers of such features will not be connected to the main body of the part, and temporary supporting structures (which can later be removed) must be fabricated as the layers are built up. By loading the polymer with ceramic or metal powder, stereolithography can be used to fabricate greenware that can be debinded and sintered to form a finished part.

Because this and the other rapid prototyping processes are rather slow, they would be appropriate production methods only for limited runs. By the same token, however, the avoidance by rapid

prototyping of expensive tooling makes it all the more attractive for limited runs. Stereolithography is perhaps the most well-developed technique for rapid prototyping, and a number of vendors provide hardware, software, and special polymers to accomplish this technique. Some of the hardware is small enough that the term *desktop manufacturing* can legitimately be applied to it.

Stereophotogrammetry

A method of generating topographic maps of fracture surfaces by the use of a stereoscopic microscope interfaced to a microcomputer which calculates the three-dimensional coordinates of the fracture surface and produces the corresponding profile map, contour plot, or carpet plot.

Stereoradiography

A technique for producing paired radiographs that may be viewed with a stereoscope to exhibit a shadowgraph in three dimensions with various sections in perspective and spatial relation.

Stereoscopic Micrographs

A pair of micrographs (or fractographs) of the same area, but taken from different angles so that the two micrographs when properly mounted and viewed reveal the structures of the objects in their three-dimensional relationships.

Stereoscopic Specimen Holder

A specimen holder designed for the purpose of making stereoscopic micrographs that allows the tilting of the specimen through the *stereo angle*.

Stereospecific Plastics

Implies a specific or definite order of arrangement of molecules in space. This ordered regularity of the molecules in contrast to the branched or random arrangement found in other plastics permits close packing of the molecules and leads to like crystallinity (for example, in polypropylene).

Stereotype Metals

Tin antimony alloys similar to Type Metals. See *White Metals* and *Babbitt Metals*.

Sterling Silver

A silver alloy containing at least 92.5% Ag, the remainder being unspecified but usually copper. Sterling silver is used for flat and hollow tableware and for various items of jewelry.

Stern-Tube Bearing

The final bearing through which a propeller shaft passes in a boat or ship.

Stick Electrode

A shop term for *covered electrode*. The coated rod electrode used for manual metal arc welding.

Stick Welding

See preferred term *shielded metal arc welding*.

Sticker Breaks

Arc-shaped *coil breaks*, usually located near the center of sheet or strip.

Stickout

See preferred term *electrode extension*.

Stick-Slip

A relaxation isolation usually associated with a decrease in the *coefficient of friction* as the relative velocity increases. Stick-slip was originally associated with the formation and destruction of interfacial junctions on a microscopic scale. This is often the basic cause. The period depends on the velocity and on the elastic characteristics of the system. Stick-slip will not occur if the static friction is equal to or less than the dynamic friction. The motion resulting from stick-slip is sometimes referred to as jerky motion. See also *spragging*.

Stiction

A term used with reference to the force necessary to overcome static friction.

Stiffness

(1) The rate of stress with respect to strain; the greater the stress required to produce a given strain, the stiffer the material is said to be. (2) The ability of a material or shape to resist elastic deflection. For identical shapes, the stiffness is proportional to the modulus of elasticity. For a given material, the stiffness increases with increasing moment of inertia, which is computed from cross-sectional dimensions.

Stiff Nut

See *self locking nut*.

Stippled Area

See *hackle*.

Stitch Weld

A line of overlapping spot welds. See preferred term *intermittent weld*.

Stitching

See *metal stitching*.

Stock

A general term used to refer to a supply of metal in any form or shape and also to an individual piece of metal that is formed, forged, or machined to make parts.

Stoichiometric

Having the precise weight relation of the elements in a chemical compound; or (quantities of reacting elements or compounds) being in the same weight relation as the theoretical combining weight of the elements involved.

Stoke (Centistoke)

The centimeter-gram-second (cgs) unit of kinematic viscosity.

Stokes Raman Line

A *Raman line* that has a frequency lower than that of the incident monochromatic beam. See also *Raman spectrum*.

Stoking (Obsolete)

See preferred term *continuous sintering*.

Stoneware

A vitreous or semivitreous ceramic ware of fine texture, made primarily from either non-refractory fireclay or some combination of clays, fluxes, and silica. Used for cookware, art wear, and tableware.

Stop

A device for positioning stock or parts in a die.

Stopoff

A material used on the surfaces adjacent to the joint to limit the spread of soldering or brazing filler metal. See also *resist*.

Stopper Rod

A device in a bottom-pour ladle for controlling the flow of metal through the nozzle into a mold. The stopper rod consists of a steel rod, protective refractory sleeves, and a graphite stopper head. See also the term *bottom-pour ladle*.

Stopping Off

(1) Applying a *resist*. (2) Depositing a metal (copper, for example) in localized areas to prevent carburization, decarburization, or nitriding in those areas. (3) Filling in a portion of a mold cavity to keep out molten metal. (4) Material applied to a surface to prevent, locally, some reaction or effect. For example, to prevent local plating or etching during such processes were to prevent adhesion of weld splatter.

Stops

Metal pieces inserted between die halves used to control the thickness of a press-molded plastic part. Not a recommended practice, because the resin will receive less pressure, which can result in voids.

Storage Life

The period of time during which a liquid resin, packaged adhesive, or prepreg can be stored under a specified temperature conditions and remain suitable for use. Also called *shelf life*.

S

Storage Modulus

A quantitative measure of the elastic properties in polymers. defined as the ratio of the stress, in phase with the strain, to the magnitude of the strain. The storage modulus may be measured in tension or flexure, compression, or shear.

Storage Stability

A measure of the ability of a lubricant to undergo prolonged periods of storage without showing any adverse conditions due to oxidation, oil separation, contamination, or any type of deterioration.

Stored-Energy Welding

Resistance welding with electrical energy accumulated electrostatically, electromagnetically, or electrochemically at a relatively low rate and made available at the higher rate required in welding.

Straddle Milling

Face milling a workpiece on both sides at once using two cutters spaced as required. See also *face milling* and *milling*.

Straightening

(1) Any bending, twisting, or stretching operation to correct any deviation from straightness and bars, tubes, or similar long parts or shapes. This deviation can be expressed as either camber (deviation from a straight line) or as total indicator reading (TIR) per unit of length. (2) A finishing operation for correcting misalignment in a forging or between various sections of a forging. See also *roll straightening*.

Straight Polarity

Direct-current arc welding circuit arrangement in which the electrode is connected to the negative terminal. A synonym for *direct current electrode negative (DCEN)*. Contrast with *reverse polarity*.

Straight-Side Press

A sheet metal forming press which has a frame made up of a base, or bed; two columns; and a top member, or crown. In most straight-side presses, steel tie rods hold the base and crown against the columns. Straight-side presses have crankshaft, eccentric-shaft, or eccentric-gear drives. In a single-action straight-side press, the slide is equipped with air counterbalances to assist the drive in lifting the weight of the slide and the upper die to the top of the stroke. Counterbalance cylinders provide a smooth press operation and easy slide adjustment. Die cushions are used in the bed for blank-holding and for ejection of the work.

Strain

The unit of change in the size or shape of a body due to force. Also known as nominal strain. The term is also used in a broader sense to denote a dimensionless number that characterizes the change in dimensions of an object during a deformation or flow process. See also *engineering strain*, *linear strain*, and *true strain* and *tensile test*.

Strain-Age Embrittlement

A loss in *ductility* accompanied by an increase in hardness and strength that occurs when low-carbon steel (especially rimmed or capped steel) is aged following *plastic deformation*. The degree of *embrittlement* is a function of aging time and temperature, occurring in a matter of minutes at about 200°C, but requiring a few hours to a year at room temperature.

Strain Aging

(1) *Aging* following plastic deformation. (2) The changes in ductility, hardness, yield point, and tensile strength that occur when a metal or alloy that has been cold worked is stored for some time. In steel, strain aging is characterized by a loss of ductility and a corresponding increase in hardness, yield point, and tensile strength.

Strain Aging or Strain Age Hardening

A spontaneous increase in hardness occurring in some materials, particularly certain steels, after they have been deformed during manufacture or service. The hardness increase is usually small but it can cause serious embrittlement. It may occur over days or even years and can be accelerated by moderate heating as occurs, for example, during hot dip galvanizing. The effect results when dissolved interstitial elements such as carbon and particularly nitrogen diffuse through the crystal lattice until they become engaged with, and hence impede the movement of, dislocations. Contrast with *strain hardening*.

Strain Amplitude

The ratio of the maximum deformation, measured from the main deformation to the free length of the unrestrained test specimen.

Strain Annealing

A technique for developing a very large grain size by annealing a material after it has received a small but critical amount of cold working. See *critical strain*.

Strain Energy Release Rate

The elastic strain energy released in unit propagation of a crack.

Strain Energy

The potential energy stored in a body by virtue of elastic deformation, equal to the work that must be done to produce this deformation. See also *elastic energy*, *resilience*, and *toughness*.

Strainer Core

In foundry practice, a perforated core in the gating system for preventing slag and other extraneous material from entering the casting cavity.

Strain Etching

Metallographic etching that provides information on deformed and under forms areas if present side-by-side. In strained areas, more compounds are precipitated.

Strain Gauge

A device for measuring small amounts of strain produced during tensile and similar tests on metal. A coil of fine wire is mounted on a piece of paper, plastic, or similar carrier matrix (backing material), which is rectangular in shape and usually about 25 mm (1 in.) long. This is glued to a portion of metal under test. As the coil extends with the specimen, its electrical resistance increases in direct proportion. This is known as bonded resistance-strain gage. Other types of gauges measure the actual deformation. Mechanical, optical, or electronic devices are sometimes used to magnify the strain for easier reading. See also rosette.

Strain Hardening

An increase in hardness and strength of metals caused by plastic deformation at temperatures below the recrystallization range. Also known as *work hardening*.

Strain-Hardening Coefficient

See *strain-hardening exponent*.

Strain-Hardening Exponent

The value of n in the relationship:

$$\sigma = K\epsilon^n$$

where

σ is the *true stress*

ϵ is the *true strain*

K , which is called the strength coefficient, is equal to the true stress at a true strain of 1.0

The strain-hardening exponent, also called “ n -value,” is equal to the slope of the true stress/true strain curve up to maximum load, when plotted on a log-log coordinates. The n -value relates to the ability of a sheet material to be stretched in metal working operations. The higher the n -value, the better the formability (stretchability).

Strain Markings

Manifestations of prior plastic deformation visible after etching of a metallographic section. These markings may be referred to as slip strain markings, twin strain markings, and so on, to indicate the specific deformation mechanism of which they are a manifestation.

Strain Point

That temperature corresponding to a specific rate of elongation of a glass fiber or a specific rate of midpoint deflection of a glass beam. At the strain point of glass, internal stresses are substantially relieved in a matter of hours.

Strain Rate

The time rate of straining for the usual tensile test. Strain as measured directly on the specimen gauge length is used for determining strain rate. Because strain is dimensionless, the units of strain rate are reciprocal time.

Strain-Rate Sensitivity (m -Value)

The increase in stress (σ) needed to cause a certain increase in plastic strain rate ($\dot{\epsilon}$) At a given level of plastic strain (ϵ) and a given temperature (T).

$$\text{Strain - rate sensitivity} = m = \left. \frac{\Delta \log \sigma}{\Delta \log \dot{\epsilon}} \right|_{\epsilon, T}$$

Strain Relaxation

Reduction in internal strain over time.

Strain Rods

(1) Rods sometimes used on gapframe metal forming presses to lessen the frame deflection. (2) Rods used to measure elastic strain, and thus stresses, in frames of metal forming presses.

Strain State

See *state of strain*.

Strand

Normally, an untwisted bundle or assembly of continuous filaments used as a unit to reinforced plastics, including slivers, tows, ends, yarn, and so forth. Sometimes a single fiber or filament is called a strand.

Strand Casting

A generic term describing *continuous casting* of one or more elongated shapes such as billets, blooms, or slabs; if two or more shapes are cast simultaneously, they are often of identical cross-section.

Strand Count

The number of *strands* in a plied *yarn* or *roving*.

Stranded Electrode

A composite filler metal electrode of stranded wires which may mechanically enclose materials to improve properties, stabilize the arc, or provide shielding.

Strand Integrity

The degree to which the individual filaments making up a *strand* or *end* are held together by the applied sizing. See also *size*.

Strand Tensile Test

A tensile test of a single resin-impregnated *strand* of any fiber.

Strap Joint

A joint formed by butting two plate edges together and laying a strap along the butt line. The strap is then joined to the individual plates by bolting, riveting, welding or brazing, etc.

S

Strada

In sampling, segments of a lot that may vary with respect to the property under study.

Strauss Test

A test for weld decay in which a specimen is boiled in a copper sulfate/sulfuric acid solution for 72 h and then bent to check for cracking.

Stray Arc/Flash

In arc welding, the unintentional striking of an arc against the component, including previously deposited weld metal, and the surface damage so caused.

Straight Current

(1) Current flowing through paths other than the intended circuit. (2) Current flowing in electrodeposition by way of an unplanned and undesired bipolar electrode that may be in the tank itself or a poorly connected electrode. (3) Unexpected electrical currents arising in processes or encountered in the environment. For example, earth return or other currents associated with tram ways can produce currents in other buried components.

Stray-Current Corrosion

(1) Corrosion resulting from direct current flow through paths other than the intended circuit. For example, by an extraneous current in the earth. (2) Electrolytic corrosion caused by stray currents in the environment. Electrical currents are found in soil as a result of its deliberate use as an earth return or as a result of accidental leakage. Such currents can cause severe corrosion of equipment at considerable distances from the location where the current enters the soil.

Strength

The maximum nominal stress a material can sustain. Always qualified by the type of stress (tensile, compressive, or shear).

Strength Coefficient

See *strain-hardening exponent*.

Stress

The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area. Stress can be normal (tension or compression) or shear. See also *compressive stress*, *engineering stress*, *mean stress*, *nominal stress*, *normal stress*, *residual stress*, *shear stress*, *tensile stress*, and *true stress*.

Stress (Glass)

Any condition of tension or compression existing within the glass, particularly due to incomplete annealing, temperature gradient, or inhomogeneity.

Stress Amplitude

One-half the algebraic difference between the maximum and minimum stresses in one cycle of a repetitively varying stress.

Stress Analysis

Any technique for determining the level and distribution of stress in complex components and structures. Examples include scale solid modeling, mathematical and computer modeling including finite element analysis and stress assisted/accelerated corrosion. Corrosion in which the rate of attack is significantly increased by stress. Where the attack causes cracking it would normally be termed *Stress Corrosion Cracking*.

Stress Concentration

(1) On a macromechanical level, the magnification of the level of an applied stress in the region of a notch, void, hole, or inclusion. (2) The local increase in stress at a crack, notch or other section change, also termed a stress riser. A component containing a crack is obviously weaker than one which is defect free but the reduction in strength is often more than would be expected simply from the reduction in cross-section. The cause can be visualized by considering a cracked bar in which the load is evenly distributed over many individual strands. Remote from the crack the strands and the load will be evenly spread across the section but at the crack the load in the severed strands will be transferred to the immediately adjacent, intact strands. The strands at the zone at the crack tip will, therefore, be subjected to their normal share of the load plus the load transferred from the severed strands. In ductile materials this zone will yield transferring load deeper into the surrounding material. However, non-ductile material will not yield and locally the stresses remain high leading to one extension of cracking at the crack tip. Stress concentrations can also be caused by holes, steps and section changes. Generalizing the sharper the step or the smaller the crack tip radius the more severe their stress concentration. See also *notch strengthening*.

Stress Concentration Factor (K_t)

A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole; K_t equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also called theoretical stress concentration factor (*S.C.F.*).

Stress Corrosion

Preferential attack of areas under stress in a corrosive environment, where such an environment alone would not have caused corrosion.

Stress-Corrosion Cracking (SCC)

(1) A cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. This excludes corrosion-reduced sections that failed by fast fracture. It also excludes intercrystalline or transcrystalline corrosion, which can disintegrate an alloy without applied or residual stress. Stress-corrosion cracking may occur in combination with *hydrogen embrittlement*. (2) Cracking resulting from the combined and concurrent effect of corrosion and a stress. Some metals are highly susceptible to cracking when stressed while

exposed to specific corrodents. In the absence of the corrodent the stress has no adverse effect and, even when both stress and the corrodent are present, the volume of metal loss to the corrosion process is usually negligible. The attack normally takes the form of cracking commencing at the surface and penetrating along a multiple branching path. The stress, almost invariably tensile, may be externally imposed or residual and the path will be either intergranular or transgranular depending upon the particular material and environment. Examples include brass in ammonia solutions and austenitic stainless steel in chloride solutions. See *steels*.

Stress Crack

(1) External or internal cracks in a plastic caused by tensile stresses less than that of its short-time mechanical strength, frequently accelerated by the environment to which the plastic is exposed. The stresses that cause cracking may be present internally or externally or may be combinations of the stresses. (2) Cracking occurring as a result of the combined and concurrent effect of the hostile environment and stress. This term is commonly applied in the context of polymeric (plastic) materials in which case the responsible environmental factor may be liquid, gaseous or radiation including light. However, the term is occasionally, perhaps increasingly, used in the case of metals as an alternative to stress corrosion. See also *crazing*.

Stress-Cracking Failure

The failure of a plastic by cracking or crazing some time after it has been placed under load. Time-to-failure may range from minutes to years. Causes include molded-in stresses, post fabrication shrinkage or warpage, and hostile environment.

Stress Cycle

The smallest segment of the stress-time function that is repeated periodically.

Stress Cycles Endured (N)

The number of cycles of a specified character (that produce fluctuating stress and strain) that a specimen has endured at any time in its stress history.

Stress Equalizing

A low-temperature heat treatment used to balance stresses in cold-work material (metals) without an appreciable decrease in the mechanical strength produced by cold working.

Stress Force (Per Unit Area)

The three basic stresses are tension, compression and shear. See *tensile test*.

Stress Fracture

See *fracture stress*.

Stress-Induced Crystallization

The production of crystals in a polymer by the action of stress, usually in the form of an elongation. It occurs in fiber-spinning

and rubber elongation and is responsible for enhanced mechanical properties.

Stress-Intensity Calibration

A mathematical expression, based on empirical or analytical results, that relates the *stress-intensity factor* to load and crack length for a specific specimen planar geometry. Also known as K calibration.

Stress-Intensity Factor

A scaling factor, usually denoted by the symbol K , used in *linear-elastic fracture mechanics* to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress-intensity factor, or the *fracture toughness*. Various subscripts are used to denote different loading conditions or fracture toughnesses:

- K_{Ic} . Plane-stress fracture toughness. The value of stress intensity at which crack propagation becomes rapid in sections thinner than those in which plane-strain conditions prevail.
- K_I . Stress-intensity factor for a loading condition that displaces the crack faces in a direction normal to the crack plane (also known as the opening mode of deformation).
- K_{Ic} . Plane-strain fracture toughness. The minimum value of K_{Ic} for any given material and condition, which is attained when rapid crack propagation in the opening mode is governed by plane-strain conditions.
- K_{ID} . Dynamic fracture toughness. The fracture toughness determined under dynamic loading conditions; it is used as an approximation of K_{Ic} for very tough materials.
- K_{Isc} . Threshold stress intensity factor for stress-corrosion cracking. The critical plane-strain stress intensity at the onset of stress-corrosion cracking under specified conditions.
- K_Q . Provisional value for plane-strain fracture toughness.
- K_{th} . Threshold stress intensity for stress-corrosion cracking. The critical stress intensity at the onset of stress-corrosion cracking under specified conditions.
- ΔK . The range of the stress-intensity factor during a fatigue cycle. See also *fatigue crack growth rate*.

Stress-Intensity Factor Range (ΔK)

In fatigue, the variation in the *stress-intensity factor* in a cycle, that is, $K_{max} - K_{min}$. See the term *fatigue crack growth rate*.

Stress-Number Curve

The S/N curve depicting fatigue properties.

Stress Raisers

(1) Design features (such as sharp corners) or mechanical defects (such as notches) that act to intensify the stress at these locations. (2) Any feature such as a section change, crack or inclusion which causes an increase in the stress in its vicinity, i.e., a stress concentration.

S

Stress Relief

Any process for reducing residual stress induced by cold working, welding, etc. The term usually implies processes which involve heating the component to some moderate temperature for a short period, typically an hour or two. As examples, stress relief of welds in normalized plain carbon steel would be at about 550°C and creep resisting alloy steels at 700°C. Simplistically, at such temperature the yield strength is greatly reduced allowing plastic deformation to convert much of the elastic strain to plastic strain. Consequently, stress relief may cause some deformation of the component and, even after stress relief, some stresses will remain. The treatment may also produce some beneficial softening of hardened areas of the heat affected zones of welds but it is usually implicit that the tensile properties of the bulk component will not be adversely affected to any significant extent. In the case of cold work material there may be useful improvements in ductility and toughness. See also *vibratory stress relief*.

Stress Range

See *range of stress*.

Stress Ratio (A or R)

The algebraic ratio of two specified stress values in a stress cycle. Two commonly used stress ratios are: (1) the ratio of the alternating stress amplitude to the mean stress, $A = S_a/S_m$; and (2) the ratio of the minimum stress to the maximum stress, $R = S_{min}/S_{max}$. See *fatigue*.

Stress Relaxation

The time-dependent decrease in stress in a solid under constant constraint at constant temperature.

Stress-Relaxation Curve

A plot of the remaining or relaxed stress as a function of time. The relaxed stress equals the initial stress minus the remaining stress. Also known as *stress-time curve*.

Stress-Relief Cracking

Cracking in the *heat-affected zone* or weld metal that occurs during the exposure of weldments to elevated temperatures during postweld heat treatment, in order to reduce residual stresses and improve toughness, or high temperature service. Stress-relief cracking occurs only in metals that can precipitation-harden during such elevated-temperature exposure; it usually occurs as *stress raisers*, is intergranular in nature, and is generally observed in the coarse-grained region of the weld heat-affected zone. Also called postweld heat treatment cracking or stress relief embrittlement.

Stress Relieving

Heating to a suitable temperature, holding long enough to reduce residual stresses, and then cooling slowly enough to minimize the development of new residual stresses.

Stress Rupture (Properties) and Creep Failure (Properties)

There are various conventions for presenting graphically the interaction between stress, temperature and time to failure for a particular

material. The term “Rupture Data” usually refers to a plot of stress on the vertical scale against temperature on the horizontal with lines on the graph identifying time to failure. This system is useful as it can also present proof stress data. See also *Larson Miller Parameter*.

Stress-Rupture Strength

See *creep-rupture strength*.

Stress-Rupture Test

See *creep-rupture test*.

Stress State

See *state of stress*.

Stress-Strain Curve

A graph in which corresponding values of stress and strain from a tension, compression, or torsion test are plotted against each other. The values of stress are usually plotted vertically (ordinates on y-axis) and values of strain horizontally (abscissas or x-axis). Also known as deformation curve and *stress-strain diagram*. See also *engineering strain* and *engineering stress*.

Stress-Strain Diagram

See *tensile test*.

Stretch-Bending Test

A simulative test for sheet metal formability in which a strip of sheet metal is clamped at its ends in lock beads and deformed in the center by a punch. Test conditions are chosen so that fracture occurs in the region of punch contact.

Stretcher Leveling

The leveling of a piece of sheet metal (that is, removing warp and distortion) by gripping it at both ends and subjecting it to a stress higher than its yield strength.

Stretcher Straightening

A process for straightening rod, tubing, and shapes by the application of tension at the ends of the stock. The products are elongated a definite amount to remove warpage.

Stretcher Strains

Elongated markings that appear on the surface of some sheet materials when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. See also the term *Lüders lines*.

Stretch Former

(1) A machine used to perform *stretch forming* operations. (2) A device adaptable to a conventional press for accomplishing stretch forming.

Stretch Forming

The shaping of a metal sheet or part, usually of uniform cross section, by first applying suitable tension or stretch and then wrapping it around a die of the desired shape. The four methods of stretch forming are stretch draw forming, stretch wrapping, compression forming, and radial draw forming. See the term *radial draw forming*.

Stretching

The extension of the surface of a metal sheet in all directions. In stretching, the flange of the flat blank is securely clamped. Deformation is restricted to the area initially within the die. The stretching limit is the onset of metal failure.

Striation (Glass)

A fracture surface marking consisting of a separation of the advancing crack front into separate fracture planes. Also known as coarse hackle, step fracture, or lance. Striations may also be called shark's teeth or whiskers.

Striation (Metals)

A fatigue fracture feature, often observed in electron micrographs, that indicates the position of the crack front after each succeeding cycle of stress. The distance between striations indicates the advance of the crack front across that crystal during one stress cycle, and a line normal to the striations indicates the direction of local crack propagation. See also *beach marks* and the term *fatigue striation* (metals).

Stribeck Curve

A graph showing the relationship between coefficient of friction and the dimensionless number ($\eta N/P$), where η is the dynamic viscosity, N is the speed (revolutions per minute for a journal), and P is the load per unit of projected area. The symbols Z and v (linear velocity) may be substituted for η and N , respectively.

Strike

(1) A thin electrodeposited film of metal to be overlaid with other plated coatings. (2) A plating solution of high covering power and low efficiency designed to electroplate a thin, adherent film of metal. (3) A defect produced during welding by accidental, brief contact of an arc welding electrode.

Striker/Striking Plate

An electric arc welding, a piece of metal, not part of the component to be welded, on which the arc is initiated immediately prior to its transfer to the joint being made. Its function is to avoid arc initiation defects on the joint.

Striking

Electrodepositing, other special conditions, a very thin film of metal that will facilitate further plating with another metal or with the same metal under different conditions.

Striking Surface

Those areas on the faces of a set of metal forming dies that are designed to meet when the upper die and lower die are brought together. The striking surface helps protect impressions from impact shock and aids in maintaining longer die life.

Stringer

In wrought materials, and elongated configuration of microconstituents or foreign material aligned in the direction of working. The term is commonly associated with elongated oxide or sulfide inclusions in steel.

Stringer Bead

A continuous weld bead made without appreciable transverse oscillation. Contrast with *weave bead*.

Stringers

Discontinuous lines of nonmetallic inclusions in the microstructure resulting from, and providing information on, deformation during manufacture.

Stringiness

The property of an adhesive that results in the formation of filaments or threads when adhesively bonded surfaces are separated.

Strip

(1) A flat-rolled metal product of some maximum thickness and width arbitrarily dependent on the type of metal; narrower than *sheet*. (2) A roll-compacted metal powder product. See also *roll compacting* and *rolled compact*. (3) Removal of a powder metal-lurgy compact from the die. An alternative to ejecting or knockout. See also *ejection*.

Strippable Coatings

Strippable coatings are those that are applied for temporary protection and that can be readily removed. They are composed of such resins as cellulose, vinyl, acrylic, and polyethylene; they can be water based, solvent-based, or hot-melt. The choice of base depends on the surface to be protected. Water-base grades are neutral to plastic and painted surfaces, whereas solvent-base types affect those surfaces. Clear vinyl strippable coatings, perhaps the most widely used, are usually applied by spraying in thicknesses of 30–40 mils. Acrylic strippable coatings impart a clear, high-gloss, high-strength temporary film to metal parts. Polyethylene strippable coatings are relatively low-cost and can be used on almost all surfaces except glass. Cellulosic strippable coatings are designed for hot-dip application. Film thicknesses range widely and can go as high as 200 mils. The mineral oil often present in these coatings exudes and coats the metal surfaces to protect it from corrosion over long periods.

Types

Vinyl coatings like those described in MIL-C-3254 specification were first developed for ships. These are called cocooning systems and are applied over chicken wire or a similar frame over the object

S

to be protected. The interstices of the chicken wire are coated by a process known as webbing. This consists of spraying a specially designed vinyl coating in a web fashion so that it coats the interstices with a very thin, spiderweb-like, fragile covering. This in turn is coated with a material similar to an ordinary strip coat vinyl by spraying. A more rigid protective coat of asphalt is then applied, following which coats of vinyl or aluminum enamel are applied. The advantages of this coating system are long life, ability to cover irregular surfaces, and easy removal. Disadvantages include a cumbersome structure, which is expensive.

Strippable, Spray or Able, Vinyl Coatings

These materials are generally applied by spraying in thicknesses of 30–40 mils. Their tensile strength runs 3.4 MPa minimum with an elongation of 200%, minimum. These materials are designed to be strippable after years of protective service. They are suitable for bright steel, aluminum, painted surfaces, wood, etc. They can also be used to protect spray booths, for aircraft protection, and on tanks, trucks, ships, and similar equipment.

Coatings can be produced in a translucent, colored affect or in a clear form so as to show any defects in the substrate. These coatings are generally sprayed from 1 to 2 mils thick and are designed for protection and covered storage or in the transportation or fabrication of tools. They can be readily removed even though film thickness is low.

Ethyl Cellulose, Type 1, and Cellulose Acetobutyrate, Type 11

These 100% coatings are designed for dip applications in a hot-melt bath of 177°C. Thickness ranges from 100 to 200 mils, depending on the protection desired. The mineral oil generally present in these coatings exudes and coats the metal surface to keep it from corroding and in a strippable condition for long periods. Tensile strength of the coatings is about 2.06 MPa minimum, with an elongation of about 90% when originally made, and 70% when aged.

The coatings are generally used on tools, steel and aluminum parts, and many other parts that can withstand the temperature of dipping. Variations of specification types can be formulated that do not exude oil, which can be objectionable and handling, particularly with electrical equipment. Pourable variations are also commercially available.

Some special types of ethyl cellulose strippable materials can be used on painted surfaces and are formulated so that these surfaces are not affected. They can be applied by spraying. Other specially designed strippable materials are also practical; some of them can be used for packaging.

Stripped Die Method

A specific method of removal of a powder metallurgy compact after pressing, which keeps it in position between the punches while the die is retracted either upward or downward until the compact is fully exposed and freed by an upward withdrawal of the upper punch.

Stripper (Adhesives)

A chemical solvent or acid that can remove an adhesive bond.

Stripper (Metals)

A plate designed to remove, or strip, sheet metal stock from the punching members during the withdrawal cycle. Strippers are

also used to guide small precision punches in close-tolerance dies, to guide scrap away from dies, and to assist in the cutting action. Strippers are made into types: fixed and movable.

Stripper Punch

A punch that serves as the top or bottom of a metal forming die cavity and later moves farther into the die to eject the part or compact. See also *ejector rod* and *knockout* (3).

Stripping

(1) Removing a coating from a metal surface. (2) Removing a foundry pattern from the mold or the core box from the core.

Strontium

A chemical element (symbol Sr), strontium is the least abundant of the alkaline-earth metals. It has a melting point about 770°C, and it decomposes in water. The metal is obtained by electrolysis of the fused chloride, and small amounts are used for doping semiconductors. Its compounds have been used for deoxidizing nonferrous alloys and for desulfurizing steel. But the chief uses have been in signal flares to give a red light, and in hard, heat-resistant greases. Strontium-90, produced atomically, is used in ship-deck signs as it emits no dangerous gamma rays. It gives a bright sign, and the color can be varied with the content of zinc, but it is short-lived. Strontium is very reactive and used only in compounds.

Compounds

Strontium nitrate is a yellowish-white crystalline powder, produced by roasting and leaching celestite and treating with nitric acid. The specific gravity is 2.96, the melting point is 645°C, and it is soluble in water. It gives a bright crimson flame, and is used in railway-signal lights and in military flares. It is also a source of oxygen, pyrotechnics, as well as a precursor for ceramic powders.

The strontium sulfate used as a brightening agent in paints is powdered celestite. Strontium sulfide, SrS, used in luminous paint, gives a blue-green glow, but it deteriorates rapidly unless sealed. Strontium carbonate, is used in pyrotechnics, ceramics, and ceramic permanent magnets for small motors.

The development of glazes for low-temperature vitreous bodies can be materially aided through the use of strontia. The added fluidity provided by strontia when replacing calcium and/or barium should promote interface reaction, improve glaze fit, while offsetting the slightly higher thermal expansion evidenced in some cases in the dinnerware glaze tested. Strontia additions to such glazes should materially increase glaze hardness and lower the solubility. Scratch resistance should be improved when replacements are made, especially at the expense of calcium and barium, which would be due, in part, to the earlier reaction of strontia enabling the glaze to clear with a minimum of pits.

Strontium hydrate loses its water of crystallization at 100°C and melts at 375°C. It is used in making lubricating greases and as a stabilizer in plastics. Strontium fluoride is produced in single crystals for use as a laser material. When doped with samarium it gives an output wavelength around 650 nm.

Strontium hexaboride, which is generally known as SrB₆, is stable to temperatures up to 2760°C, above which decomposition initiates. Possible uses for the material are energy sources when using the radioisotope, high-temperature insulation, nuclear reactor control rods, and control additives.

Strontium titanate has a melting point of 2080°C. Methods of compounding are (1) from mixed strontium carbonate and titanium dioxide, (2) from mixed strontium oxalate and titanium dioxide, and (3) from strontium titanyl oxalate. The strontium titanate is a high-dielectric constant material (225–250), which at lower temperatures has a temperature coefficient of dielectric constant somewhat higher than that of calcium titanate.

Strontium titanate can be used by itself or in combination with barium titanate in applications for capacitors and other parts.

The power factor of strontium titanate is unusually high at low frequencies with a great improvement in power factor in the neighborhood of 1 MHz. The thermal expansion of strontium titanate is linear over a wide temperature range (100°C–700°C).

Structural Adhesives

A structural adhesive is defined as a material used to transfer loads between adherends in service environments to which the assembly is typically exposed. Structural adhesives constitute about 35% of the total estimated sales of all adhesives and sealants. Their primary areas of application include automotive, aerospace, appliances, biomedical/dental construction, consumer electronics, fabrics, furniture, industrial machines, and marine and sports equipment.

The most common type of structural adhesive is classified as a chemically reactive adhesive. The most widely used materials included in this classification are of epoxies, polyurethanes, modified acrylics, cyanoacrylates, and anaerobics. Chemically reactive adhesives can be subdivided into two groups: one-component systems, which include moisture cure and heat-activated cure categories, and two-component systems, which are subdivided into mix-in and no-mix systems. One-component formulations that cure by moisture from the surrounding air or by adsorbed moisture from the surface of a substrate include polyurethanes, cyanoacrylates, and silicones. A one-component heat-activated system usually consists of two components that are premixed. Chemical families in this group include epoxies and epoxy-nylons, polyurethanes, polyimides, polybenzimidazoles, and phenolics.

Two-component mix-in systems consist of two separate components that must be metered in the proper ratio, mixed, and then dispersed. Chemical families in this group include epoxies, modified acrylics, polyurethanes, silicones, and phenolics. Two-component no-mix systems consist of two separate components that do not require careful metering because no mixing is involved. Adhesive is applied to one surface, while an accelerator is applied to a second surface. The surfaces are then joined. Modified acrylics are included in this group.

Other types of structural adhesives include evaporation or diffusion, hot-melt, delayed-tack, film, pressure-sensitive, and conductive adhesives. Evaporation or diffusion adhesives include materials based on organic solvents or water. In the solvent-base systems, which include rubbers, phenolics, and polyurethanes, the adhesive solution is coated on the porous substrates. Following solvent evaporation and/or absorption into the substrates, the surfaces are joined. Water-base adhesives comprise materials that are totally soluble or dispersive in water. Hot-melt adhesives are 100% solid thermoplastics that are very loosely classified as structural adhesives because most will not withstand elevated temperature loads without creep. Delayed-tack adhesives remain tacky following heat activation and cooling. Tack time ranges from minutes to days over a wide temperature range. Tack adhesives include styrene-butadiene copolymers, polyvinyl acetates, and polystyrene. Film adhesives are two-sided and one-sided tapes and films that are applied quickly

and easily. Examples are nylon-epoxies, elastomer-epoxies, epoxy-phenolics, and high-temperature-resistant polyimides. Pressure-sensitive adhesives are capable of holding substrates together when they are brought into contact under brief pressure at room temperature. Conductive adhesives include both electrically and thermally conductive materials that are added as fillers to the adhesive (usually epoxies). The most commonly used electrically conductive filler is silver in powder or flake form. Gold, copper, and aluminum are also used. Thermally conductive fillers include alumina (the most common), beryllia, boron nitride, and silica. See *hot-melt adhesives*, *water-base adhesives*, *pressure-sensitive adhesives*.

Structural Bond

An adhesive bond that joins basic load-bearing parts of an assembly. The load may be either static or dynamic.

Structural Ceramics

Advanced structural ceramic materials are being used increasingly for load-bearing applications. In such applications require materials that have high strength at room temperature and/or retain high strength at elevated temperatures, resist deformation (slow crack growth or creep), are damage tolerant, and are resistant to corrosion and oxidation and/or to abrasion and friction. Ceramics appropriate for such use offer a significant weight savings over metals. Applications include heat exchangers, automotive engine components such as turbocharger rotors and roller cam followers, power generation components, cutting tools, biomedical and plants, and processing equipment used for fabricating a variety of polymer, metal, and ceramic parts. The materials can be either monolithics or composites. A major obstacle to be overcome before these materials see more widespread use is their cost. Many of the processes used for fabrication are labor-intensive or have a high rejection rate, resulting in unacceptably high costs for the final products.

The most important of the bulk monolithic materials for high-temperature structural applications are silicon nitride (Si_3N_4), silicon aluminum oxynitride (sialon), silicon carbide (SiC), partially stabilized or transformation-toughened zirconia (ZrO_2), and alumina (Al_2O_3). These materials can exhibit high strengths (>500 MPa, or 70 ksi), moderate to high fracture toughness (4–14 MPa√m, or 3.6–12.7 ksi√in.), and low creep rates ($<10^{-9} \text{ s}^{-1}$) at 1300°C. Other candidates for structural applications are aluminum titanate (Al_2TiO_5), which has received much attention because of its good thermal shock resistance, and boron carbide (B_4C), the chief advantages of which are its high hardness (29 GPa, or 4.2×10^6 psi) and low density (2.50 g/cm³).

Two-phase structural ceramics include siliconized silicon carbide (Si/SiC) and ceramic-matrix composites. The former is fabricated by first making a green body, or preform, of SiC, which can be infiltrated with liquid silicon to fill the open space in the preform. Silicon contents range from about 15% to 50%. Ceramic composites are designed to have improved damage tolerance or increased toughness through the addition of second-phase reinforcements in the form of particulates, whiskers, or fibers.

Particulate-reinforced ceramics include transformation-toughened zirconia, in which ZrO_2 particulates act to deflect cracks from the main propagation path. Several whiskers-reinforced compositions are available, the most successful to date being $\text{SiC}_w\text{-Al}_2\text{O}_3$ used as cutting tools. A number of continuous fibers are available for reinforcement of polymer, metal, glass, glass-ceramic, and ceramic matrices. These include compositions of carbon and graphite, silicon carbide, silicon carboxynitride, silicon nitride, alumina, mullite, and a variety of glasses. Single-crystal fibers of sapphire are also available.

TABLE S.1
Industry, Use, Properties, and Applications for Structural Ceramics

Industry	Use	Property	Application
Fluid handling	Transport and control of aggressive fluids	Resistance to corrosion, mechanical erosion, and abrasion	Mechanical seal faces, meter bearings, faucet valve plates, spray nozzles, micro-filtration membranes
Mineral processing power generation	Handling ores, slurries, pulverized coal, cement clinker, and flue gas neutralizing compounds	Hardness, corrosion resistance, and electrical insulation	Pipe linings, cyclone linings, grinding media, pump components, electrostatic precipitator insulators
Wire manufacturing	Wear applications and surface finish	Hardness, toughness	Capstans and draw blocks, pulleys and sheaves, guides, rolls, dies
Pulp and paper	High-speed paper manufacturing	Abrasion and corrosion resistance	Slitting and sizing knives, stock-preparation equipment
Machine tool and process tooling	Machine components and process tooling	Hardness, high stiffness-to-weight ratio, low inertial mass, and low thermal expansion	Bearings and bushings, close tolerance fittings, extrusion and forming dies, spindles, metal-forming rolls and tools, coordinate-measuring machine structures
Thermal processing	Heat recovery, hot-gas cleanup, general thermal processing	Thermal stress resistance, corrosion resistance, and dimensional stability at extreme temperatures	Compact heat exchangers, heat exchanger tubes, radiant tubes, furnace components, insulators, thermocouple protection tubes, kiln furniture
Internal combustion engine components	Engine components	High-temperature resistance, wear resistance, and corrosion resistance	Exhaust port liners, valve guides, head faceplates, wear surface inserts, piston caps, bearings, bushings, intake manifold liners
Medical and scientific products	Medical devices	Inertness in aggressive environments	Blood centrifuge, pacemaker components, surgical instruments, implant components, lab ware

The favorable thermal, chemical, and tribological properties of some of the structural ceramics can also be achieved by the use of ceramic coatings on other materials such as metals. A number of the ceramic coatings are in use, including ZrO_2 , titanium nitride, titanium carbide, SiC, and diamond (see Table S.1).

Structural Foams

Expanded plastic materials having integral solid skins and porous cores that exhibit outstanding rigidity. Structural foams involve a variety of thermoplastic resins as well as urethanes.

Extending the size capabilities of molded parts beyond the limits of conventional injection molding is one of the main advantages of structural foam molding. Whereas injection moldings are usually referred to in terms of ounces and inches, foam moldings usually involve pounds and feet, despite the fact that foam density is much lower. Parts weighing 22.7 kg are not uncommon by low-pressure structural foam methods, and some molders can produce 45.4 kg parts in a single shot.

Foam Processing

Although structural foam parts are produced by several different methods, all systems disperse a gas into the polymer melt during processing, either by adding a chemical blowing agent to the compound or by inducing a gas directly into the melt. The gas creates the cellular core structure in the part. Regardless of the type or form a foaming agent used or when it is added to the melt, structural foam processes are classified as either low-pressure or high-pressure methods. Such a classification relates directly to size range, surface finish, economics, and properties of the molded part.

Low Pressure

Also known as short-shot, conventional structural foam processing methods are the most commonly used because they are the simplest and best suited for economical production of large, three-dimensional parts. In this process, a controlled mixture of resin and gas is injected into a mold creating a low cavity pressure—from 1.36 to 3.43 MPa. The mixture only partially fills the mold, and the bubbles of gas, having been at a higher pressure, expand immediately and fill the cavity. As the cells collapse against the mold surface, a solid skin of melt is formed over the rigid, foamed core.

Skin thickness is controlled by the amount of melt injected, mold temperature, type and amount of blowing agent, and temperature and pressure of the melt. With the use of multiple injection nozzles, extremely large parts can be molded; alternatively, several parts of varying sizes can be molded simultaneously in multi-cavity molds. Standard nominal wall thickness is 3.2 mm.

Another process variation, coinjection, involves the separate injection of two compatible resins. First, a solid resin is injected to form the solid, smooth skin against the mold surfaces. Then, the second material, a measured short shot containing a blowing agent, is injected to form the foamed part interior. The core material is usually a lower-cost resin than the skin material.

High Pressure

This is an expandable-mold, structural foam molding that is closer to conventional injection molding. The heating melt (with a blowing agent) is injected into the mold, creating cavity pressures of between 34 and 136 MPa. The mold is entirely filled, and the pressure prevents any foaming from occurring while the skin position solidifies against the mold surfaces.

At this point, the method departs from conventional injection molding. Mold pressure must be reduced and space provided to allow foaming to take place between the solid-skin surfaces. Depending on the type of equipment and size and configuration of the part, these two provisions are made either by withdrawing cores or by special press motions that partially open the mold halves.

Advantages

In addition to large-size capability and low-density structure, structural foam parts offer high stiffness-to-weight advantages. A 25% increase in wall thickness (over that of a solid section) can provide twice the rigidity—at equal weight—of a solid part. Strength-to-weight ratios of foam sections can be two to five times those of structural metals. Foamed parts made by any of the various methods are relatively stress-free because the foaming is done at a low pressure. For the same reason, sink marks do not occur in foamed parts behind ribs or at wall intersections.

Tooling for low-pressure structural foam molding is generally less expensive than that for injection molding because the low-pressure permits the use of lighter-weight mold materials. Tooling for high-pressure systems is more expensive than for conventional molding because of the special tooling motions involved to accommodate the foaming cycle.

Limitations

Surface finish is the most apparent difference and low-pressure structural foam parts, compared with conventional moldings. Part surfaces had a characteristic swirl pattern caused by the blowing agent, some of which becomes trapped between the mold surface and the skin of the part. The swirl pattern is both visual and tactile; surface roughness can be as much as 1000 μin . Parts that require smooth, finish surfaces require secondary operations, usually sanding, filling, and painting.

The principal process variables that control the swirl pattern are mold temperature, melt temperature, injection rate, and the nature and concentration of the blowing agent. Control of these variables can produce foamed parts with surfaces that replicate any mold surface, smooth or patterned. But this improvement is not achieved without trade-offs; changes involve slower injection rates, heating and cooling of the mold, and other alterations that increase mold costs.

Parts produced by gas counterpressure molding have a significantly reduced swirl pattern because the foaming gases are kept in solution until the solid skin is formed against mold surfaces. Surfaces of co-injected parts are comparable to those of solid, injection-molded parts. Surfaces of parts made by the high-pressure processes are comparable to those of injection-molded parts because the surface of the melt in contact with the mold solidifies while under pressure. But such parts have a “witness line,” which has the appearance of a wide parting line at the edges—where the mold opening made provision for foaming. Such areas may require touching up.

Another limitation of high-pressure foam molding is part size and shape. The high pressures and the cost of tools limit these systems too much smaller parts that can be molded economically by low-pressure systems. Most high-pressure parts are relatively flat. See also polyurethanes.

Structural Glass

(1) Flat glass, usually colored or opaque, and frequently ground and polished, used for structural purposes. (2) Glass block, usually hollow, used for structural purposes.

Structural Materials

These are construction materials that, because of their ability to withstand external forces, are considered in the design of a structural framework. Materials used primarily for decoration, insulation, or other than structural purposes are not included in this group.

Clay Products

The principal products in this class are the solid masonry units such as brick and the hollow masonry units such as clay tile or terra-cotta.

Brick is the oldest of all artificial building materials. It is classified as face brick, common brick, and glazed brick. Face brick is used on the exterior of a wall and varies in color, texture, and mechanical perfection. Common brick consists of the kiln run of brick and is used principally as a backup masonry behind whatever facing material is employed. It provides the necessary wall thickness and additional structural strength. Glazed brick is employed largely for interiors where beauty, ease of cleaning, and sanitation are primary considerations.

Structural clay tiles are burned-clay masonry units having interior hollow spaces termed cells. Such tile is widely used because of its strength, lightweight, and insulating and fire protection qualities. It size varies with the intended use.

Load-bearing tile is used in walls that support, in addition to their own weight, loads that frame into them, for example, floors and the roof. Tiles manufactured for use as partition walls, for furring, and for fireproofing steel beams and columns are classed as non-load-bearing tile. Special units are manufactured for floor construction: some are used with reinforced-concrete joints, and others with the steel beams in flat-arch and segmental-arch construction.

Architectural terra-cotta is a burned-clay material used for decorative purposes. The shapes are molded either by hand in plaster-of-paris molds or by machine, using the stiff-mud process.

Building Stones

Building stones generally used are limestone, sandstone, granite, and marble. Until the advent of steel and concrete, stone was the most important building material. Its principal use now is as a decorative material because of its beauty, dignity, and durability.

Concrete

Concrete is a mixture of cement, mineral aggregate, and water, which, if combined in proper proportions, form a plastic mixture capable of being placed in forms and of hardening through the hydration of the cement.

Wood

The cellular structure of wood is largely responsible for its basic characteristics, unique among the common structural materials. The strength of wood depends on the thickness of the cell walls. Its tensile strength is generally greater than its compressive strength. The ratio of its strength to its stiffness is much higher than that of steel or concrete; therefore, it is important that deflection be carefully considered in the design of a wooden floor system.

Laminated structural lumber is formed by gluing together two or more layers of wood with the grain of all layers parallel to the length of the member. Both laminated lumber and plywood make use of modern gluing techniques to produce a greatly improved product.

S

The principal advantages derived from lamination are the ease with which large members are fabricated and the greater strength of the built-up members. Laminated lumber is used for beams, columns, arch ribs, cord members, and other structural members.

Plywood, while also laminated, is formed from three or more thin layers of wood that are cemented or bonded together, with the grain of the several layers alternately perpendicular and parallel to each other. Plywood is generally used as a replacement for sheathing or as form lumber for reinforced concrete structures. Both laminated structural lumber and plywood have the advantage of minimizing the effects of knots, shakes, and other lumber defects by preventing them from occurring in more than core lamination at a given cross-section.

Structural Metals

Of importance in this group are the structural steels, steel castings, aluminum alloys, magnesium alloys, and cast and wrought iron.

Steel castings are used for rocker bearings under the ends of large bridges. Shoes and bearing plates are usually cast in carbon steel, but rollers are often cast in stainless steel.

Aluminum alloys are strong, lightweight, and resistant to corrosion. The alloys most frequently used are comparable with the structural steels in strength. However, because aluminum alloys have a modulus of elasticity one third that of steel, the danger of local buckling is likely to determine the design of aluminum compression members.

Magnesium alloys are produced as extruded shapes, rolled plate, and forgings. The principal structural applications are in aircraft, truck bodies, and portable scaffolding.

Composite Materials

These are engineered materials synthesized with two distinct phases and comprising a load-bearing material housed in a relatively weak protective matrix. The combination of two or more constituent materials yields a composite material with engineering properties superior to those of the constituents. The associated materials are termed polymer-matrix composites (PMCs), ceramic-matrix composites (CMCs), and metal-matrix composites (MMCs).

The principal features of a fibrous composite material are the fibers, the matrix material, and the interface region between these two dissimilar materials. This class of structural material can be classified as metallic, ceramic, or polymeric, depending on the load-bearing or reinforcing material employed. The reinforcement may be particulates, whiskers, laminated fibers, or a woven fabric. These reinforcements are bonded together by the matrix, which distributes the loading between them. Generally, the reinforcement is a fibrous or particulate material, with the latter category permitting far superior structural properties to be achieved at the expense of more-challenging fabricating technologies and higher costs.

There are numerous examples in nature where this type of microstructure, comprising a load-bearing structural phase housed in a protective matrix, is present. An example is a tree, where the trunk and branches comprise flexible cellulose fibers in a rigid lignin matrix. Development of the class of synthetic materials with this type of structure, such as fiberglass composites and graphite-epoxy laminate, revolutionized the automotive, aerospace, and sporting goods industries. However, it should be noted that composite materials have been used for centuries; for example, bricks were manufactured in ancient Egypt that featured a composite material of clay and straw.

The latest generation of advanced composite materials includes some of the lightest, strongest, stiffest, and most corrosion-resistant

materials available to the engineering community. For example, there is a striking contrast of the magnitudes of the stiffness-to-weight ratio or the strength-to-weight ratio of the commercial metals relative to those of the advanced composite materials. Whereas the specific stiffness of aluminum can be increased threefold by the addition of silicon carbide fibers to create a metal-matrix composite, the specific stiffness of graphite-epoxy, fiber-reinforced, polymeric materials can be over four times greater than the specific strength of steel. The ramifications of this comparison are immense, because of lightweight, high-strength, high-stiffness structures can be fabricated with these advanced polymeric composite materials with a weight savings of approximately 50%. This class of designs translates into superior performance for diverse products such as those in the aerospace, defense, automotive, biomedical, and sporting goods industries.

Structural Reaction Injection Molding (SRIM)

A molding process that is similar in practice to resin transfer molding. SRIM derives its name from the RIM process from which the resin chemistry and injection techniques have been adapted. The term structural is added to indicate the reinforced nature of the composite components manufactured by this process. In the SRIM process a preformed reinforcement is placed in a close mold, and a reactive resin mixture is mixed under high pressure in a specially designed mix head. Upon mixing, the reacting liquids flow at low-pressure through a runner system and fill the mold cavity, impregnating the reinforcement material in the process. Once the mold cavity has filled, the resin quickly completes its reaction. A completed component can often be removed from the mold in as little as 1 min.

Structural Shape

A piece of metal of any of several designs accepted as standard by the structural branch of the iron and steel industries.

Structure

As applied to a crystal, the shape and size of the unit cell and the location of all atoms within the unit cell. As applied to microstructure, the size, shape, and arrangement of phases. See also unit cell.

Structure Factor

A mathematically formulated term that relates the positions and identities of atoms in a crystalline material to the intensities of x-ray or electron beams diffracted from particular crystallographic planes.

Strut

A column or beam carrying a compressive load.

Stub-in

In welding, the entrapment of the electrode or filler wire in the solidifying weld metal.

Stub

The discarded end of some consumable such as a manual metallic arc welding electrode.

Stud

(1) Various components, which usually fit some larger assembly, which act as connectors, retainers, or locating devices. (2) A threaded fastener with both ends threaded, one for insertion into the main body of a component and the other end to carry a nut. For example, a set of studs would be screwed into a cylinder block prior to positioning the cylinder head and installing the nuts. Compare with studbolt.

Stud Welding

An arc welding process in which the contact surfaces of a stud, or similar fastener, and the workpiece are heated and melted by an arc drawn between them. The stud is then plunged rapidly onto the workpiece to form a weld. Partial shielding may be obtained by the use of a ceramic ferrule surrounding the stud. Shielding gas or flux may or may not be used. The two basic methods of stud welding are known as stud arc welding, which produces a large amount of weld metal around the stud base and a relatively deep penetration into the base metal, and capacitor discharge stud welding, which produces a very small amount of weld metal around the stud base and shallow penetration into the base metal. The heating processes include electric-arc, -resistance, capacitor discharge, friction, etc.

Studbolt

A threaded fastener with both ends threaded and carrying nuts at both ends. For example, a studbolt would pass through a pair of flanges to hold them together. Compare with *stud*.

Studding

Bar threaded over its full-length, often supplied in standard lengths to be cut to length as required. Also see multiple studs (1) and (2).

Styrene–Acrylonitrile (SAN)

A copolymer of about 70% styrene and 30% acrylonitrile, with higher strength, rigidity, and chemical resistance than can be attained with polystyrene alone. These copolymers may be blended with butadiene as a terpolymer or grafted onto the butadiene to make acrylonitrile–butadiene–styrene resins. They are transparent and have high heat-deflection properties, excellent gloss, chemical resistance, hardness, rigidity, dimensional stability and load-bearing capability.

Styrene–Maleic–Anhydride (SMA)

Copolymers made by the copolymerization of styrene and maleic anhydride, with higher heat resistance than the parent styrenic and acrylonitrile–butadiene–styrene families. For structurally demanding applications, SMAs are reinforced with glass fibers. Most reinforced grades contain 20 wt% reinforcement.

Styrene–Rubber Plastics

Plastics based on styrene polymers and rubbers, the styrene polymers being the greatest amount by mass.

Styrofoam Pattern

An expendable pattern of foamed plastic, especially expanded polystyrene, used in manufacturing castings by the lost foam process. See the term *lost foam casting*.

Subatomic

Particles forming an atom or processes occurring on a smaller scale than an atom.

Subboundary Structure (Subgrain Structure)

A network of low-angle boundaries, usually with misorientation less than 1° within the main grains of a microstructure.

Subcritical Annealing

Softening steels at a temperature just below the transition range, typically about 650°C for about an hour. Also termed *process annealing*. Such treatment is normally applied to heavily cold worked material so it causes the ferrite to recrystallize but does not take the carbide into solution. The resulting microstructure therefore comprises equiaxed grains of ferrite superimposed on elongated stringers or bands of spheroidized carbide. The benefits of the process compared with normalizing or full annealing include lower heating costs, less scaling and, in some cases, good machining characteristics. See *steel*, *annealing* and *transformation temperature*.

Subgrain

A portion of a *crystal* or *grain*, with an orientation slightly different from the orientation of neighboring portions of the same crystal.

Sublimation

Evaporation directly from the solid to vapor without an intermediate liquid phase.

Submerged Arc Welding

Arc welding in which the arc, between a bare metal electrode and the work, is shielded by a blanket of granular, fusible material overlying the joint. Pressure is not applied to the joint, and filler metal is obtained from the consumable electrode (and sometimes from a supplementary welding rod).

Submerged-Electrode Furnace

A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes submerged in the ceramic lining. See also *immersed-electrode furnace*.

Submicron Powder

Any powder whose particles are smaller than ~1 μm .

Submicroscopic

Below the resolution of a microscope.

Subsample

A portion taken from a *sample*. A laboratory sample may be a subsample of a gross sample; similarly, a test portion may be a subsample of a laboratory sample.

S

Subsieve Analysis

Size distribution of particles that will pass through a standard 325-mesh sieve having 44 μm openings. See the term *sieve analysis*.

Subsieve Fraction

Particles that will pass through a 44 μm (325-mesh) screen. See also sieve analysis.

Subsieve Size

See preferred term *subsieve fraction*.

Sub-Sow Block (Die Holder)

A block used as an adapter in order to permit the use of forging dies that otherwise would not have sufficient height to be used in the particular unit or to permit the use of dies in a unit with different *shank sizes*. See also *sow block*.

Substitutional Element

An alloying element with atomic size and other features similar to the solvent that can replace or substitute for the solvent atoms in the lattice and form a significant region of solid solution in the *phase diagram*. See *solution*.

Substitutional Solid Solution

A *solid solution* in which the solvent and solute atoms are located randomly at the atom sites in the crystal structure of the solution. See also *interstitial solid solution*.

Substrate

(1) The material, workpiece, or substance on which the coating is deposited. (2) A material upon the surface of which an adhesive-containing substance is spread for any purpose, such as bonding or coating. A broader term than *adherend*. (3) In electronic devices a body, board, or layer of material, on which some other active or useful material(s) or component(s) may be deposited or laid, for example, electronic circuitry laid on an alumina ceramic board. (4) In catalysts, the formed, porous, high-surface area carrier on which the catalytic agent is widely and thinly distributed for reasons of performance and economy. (5) The material underlying the surface film or outer layer.

Substrate Preparation

The set of operations, including cleaning, degreasing, and finishing applied to the base material prior to applying a coating; intended to ensure an adequate bond to the coating.

Substrate Temperature

In thermal spraying, the temperature attained by the base material as the coating is applied. Proper control of the substrate temperature by intermittent spraying or by the application of external cooling will minimize stresses caused by substrate and coating thermal expansion differences.

Substructure

Same as *sub-boundary structure*.

Subsurface Corrosion

Formation of isolated particles of corrosion products beneath a metal surface. The results from the preferential reactions of certain alloy constituents to inward diffusion of oxygen, nitrogen, or sulfur.

Subzero Machining

Using refrigerant or other means for cooling the workpiece during, or before, machining.

Subzero Treatment

Any treatment below 0°C or fahrenheit particularly cooling of steel to cause transformation of retained austenite. See *steel*.

Suck-Back

See preferred term *concave root surface*.

Suede

Also called **napped leather**. A soft-finished, chrome-tanned leather made from calf, kid, or cowhide splits, or from sheepskin. It is worked on a staking machine until it is soft and supple, and then buffed or polished on an abrasive wheel. It has a soft nap on the polished side and may be dyed any color. Suede is used for shoe uppers, coats, hats, and pocketbooks, but is now largely imitated with synthetic fabrics. **Artificial suede**, or **Izarine**, of Atlas Powder Co., has a base of rubber fabric. Fine cotton fibers dyed in colors are cemented to one side, and the underside of the sheet is beaten to make the fibers stand out until the cement hardens. The fabric looks and feels like fine suede. Some suede is also made by chemical treatment of sheepskins without staking. It has a delicate softness, but is not as wear-resistant as calfskin.

Sulfamic Acid

A white, crystalline, odorless solid, very soluble in water, but only slightly soluble in alcohol. The melting point is 178°C. The acid is stronger than other solid acids, approaching the strength of hydrochloric. It is used in bating and tanning leather, giving a silky, tight grain in the leather. An important use is for cleaning boiler and heat-exchanger tubes. It converts the calcium carbonate scale to the water-soluble calcium sulfamate, which can then be flushed off and combined with sodium chloride; it also converts the rust to ferric chloride and then to the water-soluble iron sulfamate. High purity grades are used for bleaching paper pulp and textiles, organic synthesis, gas-liberating compositions, and as a catalyst for urea-formaldehyde resins. **Ammonium sulfamate** is the ammonia salt of the acid, used as a cleanser and anodizer of metals, as a weedkiller, and for flame proofing paper and textiles.

Suds

Water or emulsion containing corrosion inhibitors and other additives used to cool and lubricate components and tooling during severe metal cutting operations.

Sulfating

The development of a layer of lead sulfate on discharged lead acid cells. It causes permanent damage as it is not reduced by subsequent charging.

Sulfidation

The reaction of a metal or alloy with a sulfur-containing species to produce a sulfur compound that forms on or beneath the surface on the metal or alloy.

Sulfide Spheroidization

A stage of overheating ferrous metals in which sulfide inclusions are partly or completely spheroidized.

Sulfide Stress Cracking (SSC)

Brittle fracture by cracking under the combined action of *tensile stress* and *corrosion* in the presence of water and hydrogen sulfide. See also *environmental cracking*.

Sulfide-Type Inclusions

In steels, nonmetallic inclusions composed essentially of manganese iron sulfide solid solutions (Fe, Mn)S. They are characterized by plasticity at hot-rolling and forging temperatures and, in the hot-worked product, appear as dove-gray elongated inclusions varying from a threadlike to oval outline. See also the term *stringer*.

Sulfinuz Process

A case hardening treatment for steel carried out in a salt bath which produces a case rich in nitrogen and sulfur and carbon having superior fatigue and fretting resistance.

Sulfochlorinated Lubricant

A lubricant containing chlorine and sulfur compounds, which react with a rubbing surface at elevated temperatures to form a protective film. There may be a synergistic effect, producing a faster reaction than with sulfur or chlorine additives alone.

Sulfonated Oil

A fatty oil that has been treated with sulfuric acid, the excess acid being washed out and only the chemically combined acid remaining. The oil is then neutralized with an alkali. Sulfonated oils are water-soluble and are used in cutting oils and in fat liquors for leather finishing. **Mahogany soap** is a name for oil-soluble petroleum sulfonates used as dispersing and wetting agents, corrosion inhibitors, emulsifiers, and to increase the oil absorption of the mineral pigments in paints. **Phosphorated oils**, or their sulfonates, may be used instead of the sulfonates as emulsifying agents or in treating textiles and leathers. They are more stable to alkalies.

Sulfone Polymers

Sulfones are amorphous engineering thermoplastics noted for high heat-deflection temperatures and outstanding dimensional stability.

These strong, rigid polymers are the only thermoplastics that remain transparent at service temperatures as high as 204°C.

Three commercially important sulfone-based resins are: polysulfone (PSU), including **Udel** and **Ultrason S**; polyarylsulfone (PAS), including **Radel**; and polyethersulfone (PES), including **Ultrason E**. These materials are claimed to offer the highest performance profiles of any thermoplastics processable on conventional screw-injection and extrusion machinery. Processing temperatures, however, are higher than those of other thermoplastics; the sulfones are processed on equipment that can generate and monitor stock temperatures in the range of 343°C–382°C.

Properties

Heat resistance is the outstanding performance characteristic of the sulfones. Service temperature is limited by heat-deflection temperature, which ranges from 174°C to 204°C. A high percentage of physical, mechanical, and electrical properties is maintained at elevated temperatures, within limits defined by the heat-deflection temperatures. The strength and stiffness of PSU and PES are virtually unaffected up to their glass-transition temperature. For example, the flexural modulus of molded parts remains above 2040 MPa at service temperatures as high as 160°C. Even after prolonged exposure to such temperatures, the resins do not discolor or degrade. Thermal stability and oxidation resistance are excellent at service temperatures well above 149°C.

The continuous service temperature limit (CSTL) for PSU is 160°C, and 180°C for PES. With respect to flammability, PES is rated V-0 per UL 94, and PSU is rated at V-2.

Electrical insulating properties are generally in the midrange among those of other thermoplastics, and they change little after heat aging at the recommended service temperatures. Dissipation factor and dielectric constant—and thus, loss factor—are not affected significantly by increased temperature or frequency.

Creep of the sulfones compared with that of other thermoplastics is exceptionally low at elevated temperatures and under continuous load. For example, creep at 99°C is less than that of acetal or heat-treat resistant ABS (acrylonitrile–butadiene–styrene) at room temperature. This excellent dimensional stability qualifies these sulfone resins for precision-molded parts.

The hydrolytic stability of these resins makes them resistant to water absorption in aqueous acidic and alkaline environments. The combination of hydrolytic stability and heat resistance results in exceptional resistance to boiling water and steam, even under autoclave pressures and cyclic exposure to hot-to-cold and wet-to-dry. PES resins have excellent resistance to hot lubricants, engine fuels, and radiator fluids, and they are resistant to gasoline. The aromatic resins are also resistant to aqueous inorganic acids, organic acids, alkalies, aliphatic hydrocarbons, alcohols, and most cleaners and sterilizing agents.

The sulfones also share a common drawback: they absorb ultraviolet rays, giving them poor weather resistance. Thus, they are not recommended for outdoor service unless they are painted, plated, or UV-stabilized.

Sulfur

Sulfur (symbol S) is one of the most useful of the elements. Its occurrence in nature is little more than 1% that of aluminum, but it is easy to extract and is relatively plentiful. In economics, it belongs to the group of “S” materials—salt, sulfur, steel, sugars, starches—whose consumption is a measure of the industrialization and the rate of industrial growth of a nation.

S

Strict environmental laws are driving the production of sulfur recovered as a by-product of various industrial operations. It is also obtained by the distillation of iron pyrites, as a by-product of copper and other metal smelting, natural gas, and from gypsum. The sterri exported from Sicily for making sulfuric acid is broken rock rich in sulfur. Brimstone is an ancient name still in popular use for solid sulfur.

Sulfur forms a crystalline mass of a pale-yellow color, with a melting point of 111°C. It forms a ruby vapor at about 416°C. When melted and cast, it forms amorphous sulfur with a specific gravity of 1.955. The tensile strength is 1 MPa, and compressive strength 22 MPa. Since ancient times it has been used as a lute for setting metals into stone. Sulfur also condenses into light flakes known as flowers of sulfur, and the hydrogen sulfide gas, H_2S , separated from sour natural gas, yields a sulfur powder.

Elemental sulfur is widely used for the synthesis of sulfur compounds. It reacts directly with virtually all elements except the noble gases. In addition to its use as a chemical intermediate, sulfur is used increasingly as a construction material. For example, sulfur-impregnated concrete is much more resistant to acid corrosion than is conventional concrete. Highways have been paved with high-sulfur asphalts.

Properties

Sulfur is twice the atomic weight of oxygen but has many similar properties and has great affinity for most metals. The crystalline sulfur is orthorhombic, which converts to monoclinic crystals if cooled slowly from 120°C. This form remains stable below 120°C. When molten sulfur is cooled suddenly, it forms the amorphous sulfur, which has a ring molecular structure and is plastic, which converts gradually to the rhombic form. Sulfur has a wide variety of uses in all industries. The biggest outlet is for sulfuric acid, mainly for producing phosphate fertilizers.

Uses

Sulfur is used for making gunpowder and for vulcanizing rubber, but for most uses it is employed in compounds, especially as sulfuric acid or sulfur dioxide.

Sulfur is used in glass as a colorant to produce golden yellows and ambers, and also with cadmium sulfide and selenium ruby glass. In sulfur amber glasses, the element is introduced as flowers of sulfur, cadmium sulfide, or sodium sulfide. Its manufacture necessitates several precautions.

Compounds

Sulfur dioxide, or sulfurous acid anhydride, is a colorless gas of the composition SO_2 , used as a refrigerant, as a preservative, in bleaching, and for making other chemicals. It liquefies at about -10°C. As a refrigerant it has a condensing pressure of 23.5 kg at 30°C. The gas is toxic and has a pungent, suffocating odor, so that leaks are detected easily. It is corrosive to organic materials but does not attack copper or brass. The gas is soluble in water, forming sulfurous acid, H_2SO_3 , a colorless liquid with suffocating fumes. The acid form is the usual method of use of the gas for bleaching.

Sulfur Dome

An inverted container, holding a high concentration of sulfur dioxide gas, used in die casting to cover a pot of molten magnesium to prevent burning.

Sulfuric Acid

An oily, highly corrosive liquid of the composition H_2SO_4 , sulfuric acid has a specific gravity of 1.841 and a boiling point of 330°C. It is miscible in water in all proportions, and the color is yellowish to brown according to the purity. It may be made by burning sulfur to the dioxide, oxidizing to the trioxide, and reacting with steam to form the acid. It is a strong acid, oxidizing organic materials and most metals. Sulfuric acid is used for pickling and cleaning metals, in electric batteries in plating baths, for making explosives and fertilizers, and for many other purposes. In the metal industries it is called dipping acid, and in the automotive trade it is called battery acid.

Uses

Sulfuric acid is used in the enameling industry for pickling purposes. The solutions vary in strength from 5% to 8%, although it is said that a 6% solution of sulfuric acid heated to 71°C–77°C will be the most effective in the pickling of sheet iron.

In making up H_2SO_4 solutions, always add the acid to the water, and never the water to the acid, as the latter method may cause a violent reaction. Sulfuric acid also has been used as a mill addition for acid-resisting enamels.

Compounds

Sulfur trioxide, or sulfuric anhydride, SO_3 , is the acid minus water. It is a colorless liquid boiling at 46°C, and forms sulfuric acid when mixed with water.

Niter cake, which is sodium acid sulfate, $NaHSO_4$, or sodium bisulfate, contains 30%–35% available sulfuric acid and is used in hot solutions for pickling and cleaning metals. It comes in colorless crystals or white lumps, with a specific gravity of 2.435 and melting point 300°C. Sodium sulfate, or Glauber's salt, is a white crystalline material used in making kraft paper, rayon, and glass. **Salt cake**, Na_2SO_4 , is impure sodium sulfate used in the cooking liquor in making paper pulp from wood. It is also used in freezing mixtures. Sodium sulfite is a white to tan crystalline powder very soluble in water but nonhygroscopic.

Sodium sulfide, Na_2S , is a pink flaky solid, used in tanneries for dehairing, and in the manufacture of dyes and pigments. The commercial product contains 60%–62% Na_2S , 3.5% $NaCl$, and other salts, and the balance water of crystallization.

Sulfurized Lubricant

A lubricant containing sulfur or a sulfur compound that reacts with a rubbing surface at elevated temperatures to form a protective film. The shear strength of the sulfide film formed on ferrous materials is lower than that of the metal but greater than that of the film formed by reaction with a chlorinated lubricant.

Sulfur Print

A print formed by placing a suitable photographic paper, previously soaked in 3% sulfuric acid, against a prepared steel surface to reveal the presence and distribution of sulfur compounds particularly manganese sulfide inclusions. These inclusions reveal the *flowlines*, i.e., the pattern of deformation, of the material during the various working operations since the material was cast.

Sum Peak

An artifact encountered in x-ray analysis during pulse pileup where two x-rays simultaneously entering the detector are counted as one x-ray, the energy of which is equal to the sum of both x-rays. See also *escape peak*.

Sun Hemp

The bast fiber is used for cordage and rope in place of jute, but is lighter in color and is more flexible, stronger, and more durable than jute. It resembles true hemp, but is not as strong. It is more properly called **sunn hemp**. It is also known as **sunn fiber**, **Indian hemp**, and **Bombay hemp**. The plant, which is a shrub, is cultivated extensively in India. The method of extraction is the same as for true hemp. The best fibers are retained locally for making into cloth. It is used in the United States for making cigarette paper and for oakum. **Madras hemp** is from another species of the same plant.

Superabrasives

Superabrasives collectively refer to diamond and cubic boron nitride (CBN), both of which are produced by synthetic means. Diamond is the hardest material known, and CBN is the second hardest. Because of their high hardness, abrasion resistance, and other unique properties, these materials find extensive use in a wide variety of abrasive or cutting applications.

The primary objective in the synthesis of diamond and CBN is to transform a crystal structure from a soft hexagonal form to a hard cubic form. In the case of carbon, for example, hexagonal carbon (graphite) would be transformed into cubic carbon (diamond). The synthesis of CBN or diamond grit is normally achieved by subjecting hexagonal carbon or boron nitride to high temperatures and high pressures with large special-purpose presses. By the simultaneous application of heat and pressure, hexagonal carbon or boron nitride can be transformed into a hard cubic form. Synthetic CBN and diamond grains can be used as loose abrasives, as bonded abrasives in grinding wheels and hones, and as bonded abrasive and single-point cutting tools. When used for the latter application, diamond and CBN are referred to as *ultrahard tool materials*.

The synthesis of diamond was first demonstrated by the General Electric Company in the 1950s. This invention subsequently led to the rapid growth of diamond for industrial applications. In addition to its high hardness, diamond is an excellent heat conductor and has an extremely low coefficient of friction. However, at temperatures above 800°C, diamond tends to graphitize, thus losing its value as a wear-resistant abrasive. Diamond suffers rapid wear and chemical dissolution (erosion) when abraded against iron. Therefore, it is not normally used as an abrasive against ferrous materials. Diamond is used extensively to grind stone, concrete, carbides, glass, ceramics, plastics, and composites. Polycrystalline diamond tool (machining) applications include nonferrous materials (aluminum–silicon alloys, copper alloys, and tungsten carbides), fiberboard, composites (graphite-epoxy, carbon–carbon, and fiberglass-reinforced plastic), and ceramics.

Like diamond, CBN also has a cubic structure. In its hexagonal close-packed structure, hexagonal boron nitride is similar to graphite and is used as a solid lubricant. **Borazon**, the General Electric trade name for CBN, was first synthesized in 1959. Unlike diamond, CBN is not very reactive with iron and therefore is used for grinding and machining of ferrous materials such as hardened steels and cast irons. Cubic boron nitride is also used for precision grinding and machining of nickel- and cobalt-base superalloys and hardfacing materials.

Superalloys

The term *superalloy* is broadly applied to iron-base, nickel-base, and cobalt-base alloys, often quite complex, which combine high-temperature mechanical properties and oxidation resistance to an unusual degree. Alloy requirements for turbosuperchargers and, later, the jet engine, largely provided the incentive for superalloy development.

Because of their excellent high-temperature performance, they are also known as high-temperature, high-strength alloys. Their strength at high temperatures is usually measured in terms of stress-rupture strength or creep resistance. For high-stress applications, the iron-base alloys are generally limited to maximum service temperature of about 649°C, whereas the nickel- and cobalt-base alloys are used at temperatures to about 1093°C and higher. In general, the nickel alloys are stronger than the cobalt alloys at temperatures below 1093°C and the reverse is true at temperatures above 1093°C. Superalloys are probably best known for aircraft-turbine applications, although they are also used in steam and industrial turbines, nuclear-power systems, and chemical- and petroleum-processing equipment. A great variety of cast and wrought alloys are available and, in recent years, considerable attention has been focused on the use of powder-metallurgy techniques as a means of attaining greater compositional uniformity and finer grain size.

Strengthening Mechanisms

Superalloys of the nickel–chromium and iron–nickel–chromium types usually contain sufficient chromium to provide that needed oxidation resistance and are further strengthened by the addition of other elements. The strengthening mechanisms include solid solution, precipitation, and carbide hardening. Most of the superalloys combine at least two and frequently all three of the above mechanisms.

Solid Solution

This is accomplished by introducing elements having different atomic sizes than those of the matrix elements, to increase the lattice strain. In addition to chromium, needed also for oxidation resistance, the elements molybdenum, columbium, vanadium, cobalt, and tungsten are effective in varying degrees as solid-solution strengtheners when added in proper balance.

Superalloys of this type, such as 16–25–6, were used in gas turbines of older design for disks, employing “hot-cold work” to obtain the required yield strength in the hub area. However, hot-cold work is not effective as a means of getting high strength at temperatures much above about 538°C.

Superconductivity

Superconductivity is a phenomenon occurring in many electrical conductors, in which the electrons responsible for conduction undergo a collective transition into an ordered state with many unique and remarkable properties. These include the vanishing of resistance to the flow of electric current, the appearance of a large diamagnetism and other unusual magnetic effects, substantial alteration of many thermal properties, and the occurrence of quantum effects otherwise observable only at the atomic and subatomic level.

The ability of certain materials, when cooled to extremely low or cryogenic temperatures, to conduct electricity with essentially zero resistance to DC current, and to AC current below certain critical high-frequency ranges, was found in the scientific community.

S

Therefore, as gas turbines operating temperatures increased and turbine disk rim temperatures appreciably exceeded 538°C, other approaches were needed.

Cobalt-base alloys are strengthened principally by solid solution hardening, usually combined with a dispersion of stable carbides.

Precipitation Hardening

Precipitation hardening is the method now employed to impart high-strength at high temperatures to most of the superalloys used for critical components of aircraft gas turbines. This includes alloys ranging from 25% nickel A-286 wheel alloy to such recent and complex high-temperature nickel-base wrought and cast turbine blade alloys as “Udimet” 700, “Nimonic” alloy 115, and IN-100.

The presence of aluminum and titanium, usually jointly, in a nickel-chromium base, with or without iron, imparts unique age-hardening characteristics through the precipitation of gamma prime phase $\{\text{Ni}_3(\text{Al,Ti})\}$.

The outstanding difference between the previously used age-hardening systems, typified by duralumin or beryllium-copper, and those utilizing gamma prime hardening lies in the fact that an alloy of the latter type can be heated in service appreciably above the optimum aging temperature without permanent loss of strength. In the conventional critical dispersion type age-hardening alloys, strength can only be restored by a complete cycle of heat treatment involving a high-temperature solution treatment and reaging.

The difference between the two types of age-hardening systems is that the aluminum-titanium hardened alloy retains most of its initial hardness (and high-temperature properties) when the overheat is removed. However, an alloy typical of the other type of system (such as beryllium copper or beryllium nickel) overages and does not regain its hardness when the overheat is removed. It is this “reversible” aging behavior, along with high resistance to overaging (agglomeration of gamma-prime hardening phase), that has led to the widespread use of aluminum-titanium age-hardened nickel-base alloys for first-stage turbine blades in commercial and advanced design jet engines. The somewhat less complex iron-nickel-chromium alloys, such as A-286 and “Incoloy” alloy 901, used for turbine disks, are similarly age-hardened, with Ni_3Ti comprising most of the age-hardening component in these two alloys. Sufficient aluminum is also present in the gamma-prime precipitate to improve structural stability.

Carbide Hardening

Carbides provide a major source of dispersed-phase strengthening and cobalt-base alloys. These alloys do not respond to age hardening with aluminum and titanium since the gamma-prime phase does not form unless substantial amounts of nickel are present. Although gamma prime $\{\text{Ni}_3(\text{Al,Ti})\}$ is the principal strengthener in the age-hardenable nickel-base alloys, important auxiliary strengthening can be obtained by precipitation of quite complex carbides. The nature of the carbides formed and their mode of distribution can usually be controlled by alloy formation in heat treatment.

Deoxidizers and Malleabilizers

In addition to the major alloying elements, small but effective amounts of malleabilizers such as boron and zirconium must be present to neutralize the effects of impurities that adversely affect hot ductility. As little as 0.005% boron is highly effective in nickel-base alloys, and zirconium, in a concentration about 10 times that

of boron, is also useful. In air melting of nickel-base alloys, magnesium is also added to fix any sulfur picked up during melting.

The high-temperature properties of the age-hardenable alloys are governed to a large degree by the hardener (aluminum plus titanium) content. However, as the hardener increases, the temperature of incipient fusion decreases and a lower temperature limit of forgeability rises, because of increased high-temperature strength, until forging is no longer practical by conventional procedures. The use of cast turbine blade alloys to meet very high temperature requirements is a natural consequence.

While other co-present elements and the amount of hot and cold workability required are also factors, it may be considered that alloys with up to 4% total hardener (aluminum plus titanium) are generally available in all common mill forms and/or fabricable by conventional methods. As the hardener increases to about 8% or 9%, wrought alloys are still available, but in progressively fewer forms, ultimately being limited to small forgings such as turbine blades, at increasingly greater cost. The commercial cast turbine blade alloys contain from about 7% to 11% total hardener and are often chosen over forgings for reason of cost or necessity or both.

Phases

Superalloys consist of a face-centered cubic (fcc) austenitic gamma phase matrix plus a variety of secondary phases. The principal secondary phases are carbides (MC , M_{23}C_4 , M_6C , and then M_7C_3) in all superalloy types and gamma prime (γ) fcc ordered $\text{Ni}_3(\text{Al,Ti})$ intermetallic compound in Ni- and Fe-Ni-based alloys. In alloys containing niobium and tantalum, the primary strengthening phase is gamma double prime (γ''), a body-centered tetragonal phase. Superalloys derive their strength from solid-solution hardeners and precipitating phases. Carbides may provide limited strengthening directly (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against excessive shear). In addition to those elements that produce solid-solution hardening and promote carbide and γ formation, and other elements (e.g., boron, zirconium, hafnium, and cerium) are added to enhance mechanical and/or chemical properties.

The three types of superalloys (Fe-Ni, Ni-, and Co-base) are further subdivided into wrought, cast, and powder metallurgy alloys. Cast alloys can be further broken down into polycrystalline, directionally solidified, and single-crystal superalloys. The most important class of Fe-Ni-base superalloys includes those alloys that are strengthened by intermetallic-compound precipitation in an fcc matrix. The most common precipitate is γ , typified by alloys A-286 and Incoloy 901, but some alloys precipitate γ' , typified by Inconel 718. Another class of cast Fe-Ni-base superalloys is hardened by carbides, nitrides, and carbonitrides; some tungsten and molybdenum may be added to produce solid-solution hardening. Other Fe-Ni-base alloys are modified in stainless steels primarily strengthened by solid-solution hardening.

The most important class of Ni-base superalloys is strengthened by intermetallic-compound precipitation in an fcc matrix. The strengthening precipitate is γ , typified by Waspaloy and Udimet 700. Another class is represented by Hastelloy X, which is essentially solid-solution strengthened, but which also derives some strengthening from carbide precipitation produced through a working-plus-aging schedule. A third class includes oxide-dispersion-strengthened (ODS) alloys, which are strengthened by dispersions of inert particles such as yttria.

Cobalt-base superalloys are strengthened by solid-solution alloying and carbide precipitation. Unlike the Fe-Ni and Ni-base alloys, no intermetallic phase has been found that will strengthen

Co-base alloys to the same degree that γ or γ' strengthens the other superalloys.

Compositions and Properties

Although factors such as tensile properties, corrosion resistance, fatigue strength, expansion characteristics, etc., are important, the creep-rupture characteristics are usually the prime requisite in the selection of a superalloy.

Vacuum Melting

Vacuum induction-melted superalloys are generally more ductile than air-melted material, permitting the use of higher aluminum plus titanium levels while still retaining adequate ductility. Vacuum induction melting accomplishes refining and also permits closer control of composition than does air melting. The vacuum arc (consumable electrode) method is widely used for superalloys, especially those employed for turbine disks. Often the electrode for the vacuum arc-melting charge is obtained from a vacuum induction melt, the end product thus combining the benefits of refining occurring in vacuum induction melting with the controlled solidification and sound ingot structure associated with the vacuum arc process. Some refining is also accomplished in the vacuum arc process, but to a lesser degree than in vacuum induction melting.

Iron-Base Superalloys

The iron-base superalloys include solid-solution alloys and precipitation-hardening (PH), or precipitation-strengthened, alloys. Solid-solution types are alloyed primarily with nickel (20% to 36%) and chromium (16% to 21%) although other elements are also present in lesser amounts. Superalloy 16-25-6, for example, the alloy designation indicating its chromium, nickel, and molybdenum contents, respectively, also contains small amounts of manganese (1.35%), silicon (0.7%), nitrogen (0.15%), and carbon (0.06%). Superalloy 20Cb-3 contains 34% nickel, 20% chromium, 3.5% copper, 2.5% molybdenum, as much as 1% columbium, and 0.07% carbon. Incoloy 800, 801, and 802 contain slightly less nickel and slightly more chromium with small amounts of titanium, aluminum, and carbon. N-155, or Multimet, an early sheet alloy, contains about equal amounts of chromium, nickel, and cobalt (20% each), +3% molybdenum, 2.5% tungsten, 1% columbium, and small amounts of carbon, nitrogen, lanthanum, and zirconium. At 732°C, this alloy has a 1000-h stress-rupture strength of about 165 MPa.

PH iron-base super alloys provide greater strengthening by precipitation of a nickel-aluminum-titanium phase. One such alloy, which may be the most well known of all iron-base superalloys, is A-286. It contains 26% nickel, 15% chromium, 2% titanium, 1.25% molybdenum, 0.3% vanadium, 0.2% aluminum, 0.04% carbon, and 0.005% boron. At room temperature, it has a tensile yield strength of about 690 MPa and a tensile modulus of 145×10^3 MPa. At 649°C, tensile yield strength declines only slightly, to 607 MPa, and its modulus is about the same or slightly greater. It has a 1000-h stress-rupture strength of about 145 MPa at 732°C. Other PH iron-base superalloys are Discoloy, Haynes 556 (whose chromium, nickel, cobalt, molybdenum, and tungsten contents are similar to that N-155); Incoloy 903 and Pyromet CTX-1, which are virtually chromium-free but high in nickel (37% to 38%) and cobalt (15% to 16%); and V-57 and W-545, which contain about 14% chromium, 26% to 27% nickel, about 3% titanium, 1% to 1.5% molybdenum, plus aluminum, carbon, and boron. V-57 has a 1000-h stress rupture

strength of about 172 MPa at 732°C and greater tensile strength but similar ductility than A-286 at room and elevated temperatures.

Nickel-Base Superalloys

Nickel-base superalloys are solid-solution, precipitation, or oxide-dispersion strengthened. All contain substantial amounts of chromium, 9% to 25%, which, combined with the nickel, accounts for their excellent high-temperature oxidation resistance. Other common alloying elements include molybdenum, tungsten, cobalt, iron, columbium, aluminum, and titanium. Typical solid-solution alloys include Hastelloy X (22% to 23% chromium, 17% to 20% iron, 8% to 10% molybdenum, 0.5% to 2.5% cobalt, 2% aluminum, 0.2% to 1% tungsten, and 0.15% carbon), Inconel 600 (15.5% chromium, 8% iron, 0.25% copper maximum, 0.08% carbon), and Inconel 601, 604, 617, and 625, the latter containing 21.5% chromium, 9% molybdenum, 3.6% columbium, 2.5% iron, 0.2% titanium, 0.2% aluminum, and 0.05% carbon. At 732°C, wrought Hastelloy X (it is also available for castings) has a 1000-h stress-rupture strength of about 124 MPa and has high oxidation resistance at temperatures to 1204°C.

The precipitation-strengthened alloys, which are the most numerous, contain aluminum and titanium for the precipitation of a second strengthening phase, the intermetallic $\text{Ni}_3(\text{Al}, \text{Ti})$ known as gamma prime (γ') or the intermetallic Ni_3Cb known as gamma double prime (γ''), during heat treatment. One such alloy, Inconel X-750 (15.5% chromium, 7% iron, 2.5% titanium, 1% columbium, 0.7% aluminum, 0.25% copper maximum, and 0.04% carbon), has more than twice the tensile yield strength Inconel 600 at room temperature and nearly 3 times as much at 760°C. Its 1000-h stress-rupture strength at 760°C is in the range of 138 to 207 MPa. Still great tensile yield strength at room and elevated temperatures and a 172-MPa stress-rupture strength at 760°C are provided by Inconel 718 (19% chromium, 18.5% iron, 5.1% columbium, 3% molybdenum, 0.9% titanium, 0.5% aluminum, 0.15% copper maximum, 0.08% carbon maximum), a wrought alloy originally that also has been used for castings. Among the strongest alloys in terms of stress-rupture strength is the wrought or cast IN-100 (10% chromium, 15% cobalt, 5.5% aluminum, 4.7% titanium, 3% molybdenum, 1% vanadium, less than 0.6% iron, 0.15% carbon, 0.06% zirconium, 0.015% boron). Investment cast, it provides a 1000-h stress-rupture strength of 517 MPa at 760°C, 255 MPa at 871°C, and 103 MPa at 982°C. Other precipitation-strengthened wrought alloys include Astroloy; D- 979; IN 102; Inconel 706 and 751; M 252; Nimonic 80A, 90, 95, 100, 105, 115, and 263; René 41, 95, and 100; Udimet 500, 520, 630, 700, and 710; Unitemp AF2-IDA; and Waspaloy. Other cast alloys, mainly investment-cast, include B-1900; IN-738X; In-792; Inconel 713C; M 252; MAR-M 200, 246, 247, and 421; NX-188; René 77, 80, and 100; Udimet 500, 700, and 710; Waspaloy; and WAZ-20.

A few of the cast alloys, such as MAR-M 200, are used to produce directionally solidified castings, that is, investment castings in which the grain runs only unidirectionally, as long as the length of turbine blades. Eliminating transverse grains improves stress-rupture properties and fatigue resistance. Grain-free alloys, or single-crystal alloys, also have been cast, further improving high-temperature creep resistance. Regarding powder-metallurgy techniques, emphasis has been on the use of prealloy powder made by rapid solidification techniques (RST) and mechanical alloying (MA), a high-energy milling process using attrition mills or special ball mills. Dispersion-strengthened nickel alloys are alloys strengthened by a dispersed oxide phase, such as thoria, which markedly increases strength at very high temperatures but only moderately so at intermediate elevated temperatures, thus limiting applications. TD-nickel, or thoria-dispersed nickel, was the first of such

S

superalloys, and it was subsequently modified with about 20% chromium, TD-NiCr, for greater oxidation resistance. MA 754 and MA 6000E alloys combine dispersion strengthening with yttria and gamma-prime strengthening.

Cobalt-Base Superalloys

Cobalt-base superalloys are for the most part solid-solution alloys, which, when aged, are strengthened by precipitation of carbide or intermetallic phases. Most contain 20% to 25% chromium, substantial nickel and tungsten and/or molybdenum, and other elements, such as iron, columbium, aluminum, or titanium. One of the most well-known, L-605, or Haynes 25, is mainly a wrought alloy, although it is also used for castings. In wrought form, it contains 20% chromium, 15% tungsten, 10% nickel, 3% iron, 1.5% manganese, and 0.1% carbon. At room temperature, it has a tensile yield strength of about 462 MPa, and at 871°C about 241 MPa. Its 1000-h stress-rupture strength at 815°C is 124 MPa. The more recent Haynes 188 (22% chromium, 22% nickel, 14.5% tungsten, 3% iron, 1.5% manganese, 0.9% lanthanum, 0.35% silicon, and 0.1% carbon), which was developed for aircraft-turbine sheet components, provides roughly similar strength and high oxidation resistance to above 1093°C. MP35N (35% nickel, 20 chromium, 10 molybdenum) is a work-hardening alloy used mainly for temperature corrosion-resistant fasteners. Another alloy, S-816, contains equal amounts of chromium and nickel (20% each), equal amounts of molybdenum, tungsten, columbium, and iron (4% each), and 0.38% carbon. Primarily a wrought alloy, although also used for castings, it has a 1000-h stress-rupture strength of 145 MPa at 815°C. Other casting alloys include AiResist 13, 213, and 215; Haynes 21 and 31, the latter also known as X-40; Haynes 151; J-1650; MAR-M 302, 322, 509, and 918; V-36; and WI-52. Their chromium content ranges from 19% (AiResist 215) to 27% (Haynes 21), and some are nickel free or low in nickel. Most contain substantial amounts of tungsten or tantalum, and various other alloying elements. Among the strongest in terms of 1000-h stress-rupture strength at 815°C are Haynes 21 and 31—290 MPa and 352 MPa, respectively.

Fabrication

Forging and Hot Working

Many of the commercial nickel-base age-hardenable superalloys can be forged or hot-worked with varying degrees of ease. As has been indicated, the top side of the forging temperature range is limited by such considerations as incipient fusion temperature, grain size requirements, tendency for “bursts,” etc., while the lower side by the stiffness and ductility of the alloy. The recommendations of the metal producer should be sought for optimum forging practice for a given alloy.

The hot extrusion process increases the gamut of superalloys compositions that can be hot-worked. By the use of a suitable sheath on the extrusion billet, otherwise unworkable alloys can be reduced to bar by hot extrusion. In some instances, mild steel has been used for a sheath, while in others, nickel-chromium alloys such as Nimonic alloy 75 and Inconel alloy 600 have been employed. Some of the very high-speed hot extrusion processes may be of value in hot-working the more refractory superalloys.

Heat Treatment

The conventional heat-treating equipment and fixtures are generally suitable for nickel alloys, and austenitic stainless steels are also

applicable to the nickel-base high-temperature alloys. Nickel-base alloys are more susceptible to sulfur and lead embrittlement than iron-base alloys. It is therefore essential that all foreign material, such as grease, oil, cutting lubricants, marking paints, etc., be removed by suitable solvents, vapor greasing, or other methods, before heat treatment.

When fabricated parts made from thin sheet or strip of age-hardening alloys such as Inconel alloy X-750 must be annealed during and after fabrication, it is desirable, especially in light gauges, to provide a protective atmosphere such as argon or dry hydrogen to lessen the possibility of surface depletion of the age-hardening elements. This precaution may not be as necessary in heavier sections, since the surface oxidation involves a much smaller proportion of the effective cross-section.

It is usually necessary after severe forming, or after welding, to apply a stress relief anneal (above 899°C) to assemblies fabricated from aluminum-titanium age-hardenable nickel-base alloys prior to aging. It is vitally important to heat the structure rapidly through the age-hardening temperature range of 649°C–760°C (which is also the low ductility range) so that stress relief can be achieved before any appreciable aging takes place. This is conveniently done by charging into a furnace at or above the desired annealing temperature. It has been found at times that the efficacy of this procedure has been vitiated in large welded structures by charging onto a cold car, resulting in a slower and nonuniform heating of the fabricated part when run into the hot furnace. Contrary to expectations, little difficulty has been encountered with distortion under the aforementioned rapid heating conditions. In fact, distortion of weldments of substantial size has been reported to be less than by conventional slow-heating methods.

Forming

All of the wrought nickel-base alloys available as sheet can be formed successfully into quite complex shapes and having much plastic flow. The lower-strength Inconel alloy 600 and Nimonic alloy 75 offer few problems. The high-strength age-hardening varieties, processed in the annealed condition, can be subjected to a surprising amount of cold work and deformation, provided sufficient power is available. Explosive forming has also been successfully employed on a number of nickel-base alloys.

Machining

All of the alloys discussed can be machined, the strongest and highest hardener content materials causing the most difficulty. The recommendations of the metal producer should be followed with respect to Altamont condition of heat treatment, type of tool, speed and feed, cutting lubricant, etc. Wrought alloys of quite high hardener content, such as Inconel alloy 700 and Udimet 500, although difficult to handle, can be machined with reasonable facility using high-speed-steel tools of the tungsten-cobalt type, and cemented carbide tools of the tungsten-cobalt and tungsten-tantalum-cobalt type.

Various electroerosion processes have been successfully used on a number of the age-hardened superalloys and, at hardener levels, may be necessary for some operations such as drilling.

Welding

Inconel alloy 600, Nimonic alloy 75, and other nickel-base alloys of the predominantly solid-solution strengthened type offer no serious problems in welding. All of the common resistance and

fusion welding processes (except submerged arc) are regularly and successfully employed.

In handling the wrought superalloys age-hardened with gamma prime, it is necessary to observe certain precautions. Material should be welded in the annealed condition to minimize the hazard of cracking in weld or parent metal. If the components to be joined to have been severely worked or deformed, they should be stress-relief-annealed before welding by charging into a hot furnace to ensure rapid heating to this stress-relieving temperature. Similarly, weldments should be stress-relieved before attempting to apply the 704°C age-hardening treatment.

Where subassemblies must be joined in the age-hardened condition, the practice of "safe ending" with a compatible nonaging material prior to age hardening can be usefully employed. The final weldments joining the fully age-hardened components are then made on the "safe ends."

Such new welding processes as "short arc," electron, and laser beam have come into increasing use and have been helpful in joining some of the very high hardener content alloys.

Brazeing

The solid solution type chromium-containing alloys, such as Inconel alloy 600, are quite readily brazed, using techniques and brazing filler metals applicable to the austenitic stainless steels. Generally speaking, it is desirable to braze annealed (stress-free) material to avoid embrittlement by the molten braze metal. Where brazing filler metals are employed that melt above the stress-relieving temperature, a prior anneal is usually not needed. As with the stainless steels, dry hydrogen, argon, and helium atmospheres are used successfully; and vacuum brazing is also very successfully employed.

The age-hardened nickel-base alloys containing titanium and aluminum are rather difficult to braze, unless some method of fluxing, solid or gaseous, is used. Alternatively, the common practice is to preplate the areas to be furnace brazed with 0.01 to 0.03 mm of nickel, which prevents the formation of aluminum or titanium oxide films and permits ready wetting by the brazing filler metal.

Silver brazing filler metals can be used for lower temperature applications. However, since the nickel-base superalloys are usually employed for high-temperature applications, the higher melting point and stronger and more oxidation-resistant brazing filler metals of the Ni-Cr-Si-B type are generally used. The silver-palladium-manganese and palladium-nickel filler metals also provide useful brazing materials for intermediate service temperatures.

Superbronze

A name applied to brasses containing both aluminum and manganese. They are ordinarily high brasses with 2%–3% manganese and 1–6 aluminum, with sometimes also some iron. They have greatly increased strength and hardness over the original brasses, but the ductility is reduced and they are difficult to work and machine. The early superbronze was known as **Heusler alloy**. Muntz metal is also frequently modified with manganese, iron, and aluminum. The alloys are used where high strength and corrosion resistance are required, and they are often marketed under trade names. The name *superbronze* is a shop term rather than a technical classification, and thus the name is often applied to any hard, high-strength, heat-treatable, copper-base alloy.

This current is referred to as supercurrent and is carried on the surface of the superconductor within a particular depth characteristic of the material.

Until recently, superconductivity was only seen in materials at fantastically cold temperatures not exceeding 23 K (–250°C) in the intermetallic compound Nb₃Ge. This meant that all superconductors had to be cooled with liquid helium, which is expensive and cumbersome to handle. Applications for superconductors were quite limited. The main use was for nuclear magnetic resonance scanners used by hospitals to examine soft tissue without surgery. Nuclear magnetic resonance scanners tap the intensely powerful magnetic fields that superconductors can be made to generate.

However, in August 1986, researchers discovered a compound of the metals lanthanum, barium, and copper, along with oxygen, that would superconduct at 35 K (–238°C).

Following this discovery, researchers brought about a dramatic jump in T_c 93 K (with an onset temperature of 98 K) by substituting yttrium for lanthanum, while roughly switching the +2 and +3 ion ratios.

Superconductors

Superconductors are solid crystalline materials whose electrical resistance drops significantly as temperature decreases. Until recently, at temperatures approaching close to absolute zero (–272°C) were required for their resistivity to vanish. Some of the metals exhibiting superconductivity at near absolute zero include iridium, lead, mercury, columbium, tin, tantalum, vanadium, and many alloys and chemical compounds. Alloys considered among the best commercially available are lead–molybdenum–sulfur, columbium-10, and columbium–titanium.

In recent years, alloys and compounds have been developed that are superconductive at temperatures substantially above absolute zero. These include a compound of lanthanum, strontium, copper, and oxygen, which is superconductive at –240°C, and a barium–yttrium–copper oxide, which is superconductive at –183°C. A two-phase ceramic superconductor has been developed in which one of the phases is superconductive at –33°C. It is basically copper oxide containing barium and yttrium.

Properties and Processing

Because J_c is higher in single crystals than in polycrystalline materials, it can be increased by minimizing the presence of grain boundaries. This is done by single-crystal growth or techniques such as melt texturing, where grain boundaries become highly directionalized to allow for significantly less random disruption of current flow. Here, the grain boundaries become predominately parallel to the copper–oxygen chains (the direction of current flow) in all the crystals. Consequently, the microstructure consists of long, needle-like grains that are parallel and intermeshed.

Single crystals have been grown epitaxially by sputtering (as well as by pulsed Excimer laser deposition and electron beam epitaxy). Good deposition can be achieved when the material is reactively sputtered in an oxygen-containing environment from three separate metallic targets (yttrium, barium, copper) simultaneously. This is known as triode sputtering and allows for tight control of stoichiometry. Following this, as with bulk samples, the films typically must be annealed in pure oxygen at –500°C. Samples also must be slow cooled to 300°C, as gravimetric analysis shows that the capability of the compound to absorb more oxygen into its crystal structure increases with decreased temperature down to 300°C. Annealing can be successfully accomplished below 300°C by use of an oxygen-ion bombardment.

The greatest reproducibility of results in single-crystal formation has come when using single-crystal SrTiO₃ as the epitaxy substrate.

S

Some success has been found in depositing single crystals on single-crystal MgO, which has a much lower dielectric constant than SrTiO₃.

Applications

There are a number of practical applications of superconductivity. Powerful superconducting electromagnets guide elementary particles in particle accelerators, and they also provide the magnetic field needed for magnetic resonance imaging (MRI). Ultrasensitive superconducting circuits are used in medical studies of the human heart and brain and for a wide variety of physical science experiments. A completely superconducting prototype computer has even been built.

Most superconductive applications that have been considered to have reasonable possibility of being achieved in the next few years involve thin-film deposition of these materials. Thin films clearly have a higher J_c advantage over bulk superconductors.

Photovoltaic substances, for example, if interfaced with a superconductor, can act as signal detectors (e.g., infrared devices) because they will be sensitive to the most minute electrical fields.

One of the potential uses of the newer superconductors is for making more powerful and efficient electromagnets that could be used in trains to levitate them above their tracks, and thus make train speeds of hundreds of miles per hour possible.

Superconductors—Materials

Superconductors are materials that exhibit a complete disappearance of electrical resistance on lowering the temperature below a critical temperature (T_c). For all superconductors presently known, as is the critical temperatures are well below room temperature, and they are usually attained by cooling with liquefied gas (helium or nitrogen), either at or below atmospheric pressure. A superconducting material must also exhibit perfect diamagnetism, that is, complete exclusion of an applied magnetic field from the bulk of the superconductor. Superconductivity permits electric power generators and transmission lines to have capacities many times greater than recently possible. It also allows the development of levitated transit systems capable of high speeds and provides an economically feasible way of producing the large magnetic fields required for the confinement of ionized gases and controlled thermonuclear fusion.

Superconductivity is observed in a broad range of materials. These include more than half of the metallic elements and a wide range of compounds and alloys. To date, however, the materials that have received the most attention are niobium–titanium superconductors (the most widely used superconductor), A15 compounds (in which class the important intermetallic Nb₃Sn lies), ternary molybdenum chalcogenides, and high-temperature ceramic superconductors. The chalcogenides and ceramics, however, are in the development stages.

Niobium–titanium superconductors are actually composite wires that consist of Nb–Ti for filaments (<10 μ m in diameter) and that it is an oxygen-free, high-purity (99.99%) copper matrix. In commercially pure aluminum (alloy 1100, 99.0%) and copper–nickel alloys (typically in concentrations of 90:10 or 70:30), matrices have also been utilized. The filament alloy most widely used is Nb–46.5Ti. Binary Nb–Ti compositions in the range of 45%–50% Ti exhibit T_c values of 9.0–9.3 K. Composite conductors containing as few as one to as many as 25,000 filaments have been processed by advanced extrusion and wire-drawing techniques. The primary applications for Nb–Ti superconductors are magnets for use in magnetic

resonance imaging (MRI) devices used in hospitals and high-energy physics pulsed accelerator-magnet applications. An example of the latter application is the Superconducting Supercollider for studying the elementary particles of which all matter is composed and the forces through which matter interacts.

A15 superconductors are brittle superconductors and brittle intermetallic A₃B compounds with a body-centered cubic crystal structure. Of the 76 known A15 compounds, 46 are known to be superconducting. Because of its ease of fabrication, Nb₃Sn is also assembled into multifilamentary wires. Applications for Nb₃Sn-base superconductors include large commercial magnets, power generators and power transmission lines, and devices for magnetically confining high-energy plasma for thermonuclear fusion.

The ternary molybdenum chalcogenides represent a vast class of materials whose general formula is M₁₂Mo₆X₈, where M is a cation and X a chalcogen (sulfur, selenium, or tellurium). Most of the research on these materials has been centered around PbMo₆S₈ and SnMo₆S₈, the former having a T_c of 14–15 K.

High-temperature superconductors (T_c values exceeding 90 K) are ceramic oxides in wire, tape, or thin-film form. The systems being studied include Y–Ba–Cu–O (most notably YBa₂Cu₃O₇), Bi–Sr–Ca–Cu–O, and Ti–Ba–Ca–Cu–O.

Type I superconductors lose this characteristic (perfect diamagnet in a weak magnetic field) at a specified field of strength; Type II loses it progressively over a range of field strength.

Supercooling

(1) Cooling of a substance below the temperature at which a change of state would ordinarily take place without such a change of state occurring, for example, the cooling of a liquid below its freezing point without freezing taking place; this results in a *metastable* state. (2) Cooling, without a phase transformation occurring, below a temperature at which transformation would occur under equilibrium conditions. The term is often used with particular reference to the rapid cooling of molten metal to below its normal freezing temperature or range. This promotes the formation of abnormally large numbers of the nuclei that start solidification and hence leads to a very fine grain size.

Supercritical Fluids

SCFs are fluids which, when compressed and heated above a critical pressure and temperature, have diffusion properties similar to those of gases and density similar to those of liquids and, thus, are efficient solvents. Critical parameters (pressure, temperature, and density, respectively) for **carbon dioxide** are 7.4 MPa, 31°C, and 471 kg/m³; **water**, 22 MPa, 374°C, and 332 kg/m³; **hydrogen**, 1.3 MPa, –240°C, and 33 kg/m³; **ammonia**, 11.3 MPa, 132°C, and 235 kg/m³; and **methyl alcohol**, or **methanol**, 8 MPa, 240°C, and 277 kg/m³.

Current and potential applications for SCFs, especially carbon dioxide and water, stem largely from regulatory pressures on ecology and safety, and health trends. They were first used in the 1970s for decaffeinating coffee and tea, replacing trichloroethylene and methylene chloride, have replaced ethylene chloride in spice extraction, and have been recently introduced for metal cleaning, deasphalting, and spray painting without volatile organic compounds. Emerging or potential uses for carbon dioxide include ethanol purification: extraction of acetone from antibiotics, fat and cholesterol from egg yolks, and vitamin E from soybean oil and soil remediation. Carbon dioxide, being nonpolar, is effective in removing nonpolar contaminants from virtually any matrix and may prove

economical for on-site removal of organic soil contaminants that do not easily volatilize.

Union Carbide's Unicarb process uses a compressed gas, usually carbon dioxide, in the supercritical state to replace most of the solvent in conventional and high-solids topcoatings as well as in primers to reduce volatile organic compounds by as much as 80% and increase transfer efficiency by reducing overspray. Concern about the known human carcinogen perchloroethylene in dry-cleaning processes may have driven some 10% of the 30,000 such establishments in North America to supercritical carbon dioxide systems by the year 2015.

Water has potential for treating various organic substances by supercritical oxidation. Organic liquids and gases mix with the water and are transformed into carbon dioxide and water while in organics dissolve only slightly, allowing them to concentrate and be recovered. Virtually all of the organics are destroyed. Potential abounds for waste treatment at chemical, pulp and paper, and weapons plants.

Water is also in contention for soil remediation, having proved effective in removing virtually all of the polycyclic aromatic hydrocarbons in soil. It is aimed at some 2000 sites in the United States and Canada where town gas has been made from coal.

Supercritical

Any action that takes a system or material past some critical point.

Supercritical Fluid

Water or other material that is pressurized to such an extent, that is, beyond the supercritical pressure, such that on heating the fluid does not boil in the conventional sense. It does not change from an identifiable liquid phase to an identifiable gas phase, there is no change in density, no latent heat is involved, and there is no physical interface such as exists normally between water and steam.

Supercritical Pressure

The pressure at which a substance becomes a supercritical fluid. For water, it is 3,208 lbs per sq in absolute.

Superficial Hardness Test

See *Rockwell superficial hardness test*.

Superfines

The portion of a metal powder that is composed of particles smaller than a specified size, usually 10 μm .

Superfinishing

An abrasive process utilizing either a curved bonded honing stick (stone) for a cylindrical workpiece or a cup wheel for flat and spherical work. A large contact area, 30% approximately, exists between workpiece and abrasive. The object of superfinishing is to remove surface fragmentation and to correct any inequalities in geometry, such as grinding feed marks and chatter marks. Also known as microhoning. See also *honing*.

Superheating

(1) Heating of a substance above the temperature at which a change of state would ordinarily take place without a change of state

occurring, for example, the heating of a liquid above its boiling point without boiling taking place; this results in a metastable state. (2) Any increment of temperature above the melting point of a metal; sometimes construed to be any increment of temperature above normal casting temperatures introduced for the purpose of refining, alloying, or improving fluidity. (3) Heating, without a phase transformation occurring, above a temperature at which transformation could occur under equilibrium conditions. (4) Heating molten metal well above its melting point to improve fluidity, etc., during casting.

Superlattice

See *ordered structure*.

Superplastic Forming

This is a process for shaping superplastic materials, a unique class of crystalline materials that exhibit exceptionally high tensile ductility. Superplastic materials may be stretched in tension to elongation's typically in excess of 200% and more commonly in the range of 400%–2000%. There are rare reports of a higher tensile elongation's reaching as much as 8000%. The high ductility is obtained only for superplastic materials and requires both the temperature and rate of deformation (strain rate) to be within a limited range. The temperature and strain rate required depend on the specific material. A variety of forming processes can be used to shape these materials; most of the processes involve the use of gas pressure to induce the deformation under isothermal conditions at the suitable elevated temperature. The tools and dies used, as well as the superplastic material, are usually heated to the forming temperature. The forming capability and complexity of configurations producible by the processing methods of superplastic forming greatly exceed those possible with conventional sheet forming methods in which the materials typically exhibit 10%–50% tensile elongation.

Processes

Superplastic forming typically utilizes a gas pressure differential across the superplastic sheet to induce to superplastic deformation and cause forming. Two processes have been developed: blow forming and movable-tool forming.

Blow Forming

Where gas pressure alone is used, the process is term *blow forming*. Blow forming utilizes tooling heated to the superplastic temperature, and the gas pressure differential is usually applied according to a time-dependent schedule designed to maintain the average strain rate within the superplastic range. The tools and the superplastic sheet are heated to the same temperature, and the gas pressure is applied to cause a creep-like plastic stretching of the sheet that eventually contacts and takes the shape of the configuration die.

Movable-Tool Forming

For relatively deep shapes, forming methods involving movable tools combined with gas-pressure forming may permit greater thinning control and reduced forming times as compared with the blow-forming method. One method is essentially the same as the blow-forming process, except that the die may be moved

S

during the forming process. Another method uses a more complex sequence. The bubbleplate holds the superplastic sheet in place and prevents gas breakage.

The plug-assisted forming method involves a movable die that is pushed into and stretches the superplastic sheet material, followed by the application of gas pressure on the same side of the sheet as the movable die. In snap-back forming, the sheet is first billowed by tree forming with gas pressure imposed on the movable-tool side of the sheet; the tool is then moved into the billowed sheet, and finally, the gas pressure is imposed on the opposite side of the sheet to form the superplastic material onto the tool.

Diffusion Bonding

Diffusion bonding, also known as diffusion welding, is sometimes used in conjunction with superplastic forming to produce parts of complexity not possible with a single-sheet forming process. Diffusion bonding is a solid-state joining process in which two or more materials are pressed together under sufficient pressure and at a sufficiently high temperature to result in joining. In diffusion bonding, there is usually little permanent deformation in the bulk of the parts being joined, although local deformation does occur at the interfaces on a microscopic scale. Because interfacial contamination, such as oxidation, will interfere with the bonding mechanisms, the process is usually conducted under an inert atmosphere, such as vacuum or inert gas.

Some superplastic materials are ideally suited for processing by diffusion bonding, because they deform easily at the superplastic temperature, and this temperature is consistent with that required for diffusion bonding. The most suitable alloys tend to have a high solubility for oxygen and nitrogen, so that these contaminants can be removed from the surface by diffusion into the base metal. For example, titanium alloys fall into this class and are readily diffusion bonded. Aluminum alloys form a very thin but tenacious oxide film and are therefore quite difficult to diffusion bond. For certain materials, and under conditions of proper processing, the diffusion-bond interfacial strength can be equal to that of the parent base material. It has been found that metals processed to fine grain size, as required for superplastic deformation, are the most suitable for diffusion bonding because they require lower bonding pressure than a coarse-grain metal of the same alloy composition.

Combined Methods

The processing conditions for superplastic forming and diffusion bonding are similar, both requiring an elevated temperature and benefiting from the fine grain size. Consequently, a combined process of superplastic forming with diffusion bonding has been developed that can produce parts of greater complexity than single-sheet forming alone. The combined process of superplastic forming and diffusion bonding can involve multiple-sheet forming after localized diffusion bonding, producing expanded structures and sandwich configurations of various types. It is also possible to form a sheet superplastically onto, and diffusion bonded to, a separate piece of material thereby producing structural configurations much more like forgings than sheet metal structures. There are other joining methods that have also been utilized as alternatives to diffusion bonding, such as spot welding, and have been combined with superplastic forming to produce complex structures.

Applications

There are a number of commercial applications of superplastic forming and combined superplastic forming and diffusion

bonding, including aerospace, architectural, ground transportation, and numerous miscellaneous uses. Examples are wing axis panels in the Airbus A310 and A320, bathroom sinks in the Boeing 737, turbo-fan-engine-cooling duct components, external window frames in the space shuttle, front covers of slot machines, and architectural siding for buildings.

Superplastic Forming (SPF)

A strain rate sensitive sheet metal forming process that uses characteristics of materials exhibiting high tensile elongation. Superplastic forming methods include: blow molding, in which gas pressure is imposed on a superplastic diaphragm, causing the material to form into the die configuration; vacuum forming, a process similar to blow molding except that the forming pressure is limited to atmospheric pressure (100 kPa) versus the maximum pressure of 700–3400 kPa for blow molding; thermoforming methods adapted from plastics technology (see *thermoforming*), which involve a moving or adjustable die member in conjunction with gas pressure or vacuum; and superplastic forming/diffusion bonding (SPF/DB), which combines blow molding and solid-state bonding. See also *diffusion bonding* and *superplasticity*.

Superplasticity

(1) The ability of certain metals (the most notably aluminum- and titanium-base alloys) to develop extremely high tensile elongation's at elevated temperatures and under controlled rates of deformation. (2) The ability to accept very large amounts of deformation often greater than 2000% elongation, without cracking or necking. The phenomenon typically occurs in very fine grained material deformed at temperatures and strain rates such that progressive deformation is matched by continuous recrystallization and recovery at a rate sufficiently rapid to maintain the fine grain size. The temperature is typically about half the melting point on the absolute scale, and the strain rate is usually low compared with industrial manufacturing and testing practice. If the circumstances are correct than any neck which tends to form will become a site for an increase in strain rate with consequent increase in stress at work hardening. Deformation will therefore cease at this point and be transferred to material elsewhere.

Superpolymers

Many plastics developed in recent years can maintain their mechanical, electrical, and chemical resistance properties at temperatures over 213°C for extended periods of time. Among these materials are polyimide, polysulfone, polyphenylene sulfide, polyarylsulfone, novaloc epoxy, aromatic polyester, and polyamide-imide. In addition to high-temperature resistance, they have in common high strength and modulus of elasticity, and excellent resistance to solvents, oils, and corrosive environments. They are also high in cost. Their major disadvantage is processing difficulty. Molding temperatures and pressures are extremely high compared to conventional plastics. Some of them, including polyimide and aromatic polyester, are not molded conventionally. Because they do not melt, the molding process is more of a sintering operation. One indication of the high-temperature resistance of the superpolymers is their glass transition temperature of well over 260°C, as compared to less than 177°C for most conventional plastics. In the case of polyimides, the glass transition temperature is greater than 427°C and the material decomposes rather than softens when heated excessively. Aromatic polyester, a homopolymer also known as polyoxybenzoate, does not melt, but at 427°C can be made to flow in a nonviscous manner similar to metals. Thus, filled and unfilled forms and parts can be made by hot sintering, high-velocity forging, and plasma spraying.

Notable properties are high thermal stability, good strength at 316°C, high thermal conductivity, good wear resistance, and extra-high compressive strength. Aromatic polyesters have also been developed for injection and compression molding. They have long-term thermal stability and a strength of 20 MPa at 288°C. At room temperature, polyimide is the stiffest of the group with a top modulus of elasticity of 51,675 MPa, followed by polyphenylene sulfide with a modulus of 33,072 MPa. Polyarylsulfone has the best impact resistance of the superpolymers with impact strength of 0.27 kg · m/cm (notch).

Polyetherimide (PEI) is an amorphous thermoplastic that can be processed with conventional thermoplastic processing equipment. Its continuous-use temperature is 170°C, and its deflection temperature is 200°C at 2 MPa. The polymer also has inherent flame resistance without use of additives. This feature, along with its resistance to food stains and cleaning agents, makes it suitable for aircraft panels and seat component parts. Tensile strength ranges from 103 to 165 MPa. Flexural modulus at room temperature is 3300 MPa.

Polyimide (PI) foam is a spongy, lightweight, flame-resistant material that resists ignition up to 427°C and then only chars and decomposes. Some formulations result in harder materials that can be used as lightweight wallboard or floor panels while retaining fire resistance.

Aromatic polyketones are high-performance thermoplastics, which include polyetheretherketone (PEEK), glass transition temperature of 143°C and melting point of 335°C; polyetherketone (PEK), glass transition temperature of 154°C; polyetherketoneketone (PEKK), glass transition temperature of 154°C and melting point of 335°C; polyaryletherketone (PAEK), glass transition temperature of 170°C and melting point of 380°C. Glass fiber reinforcement improves the strength, stiffness, and dimensional stability of these materials. In addition, there are various ketone-based copolymers.

Supersaturated

A metastable solution in which the dissolved material exceeds the amount the solvent can hold and normal equilibrium at the temperature and other conditions that prevail. See *solution*.

Supersonic

Pertains to phenomenon in which the speed is higher than that of sound. Not synonymous with ultrasonic; see also *ultrasonic frequency*.

Supplemental Operation

See *secondary operation*.

Support Pins

Rods or pins of precise length used to support the overhang of irregularly shaped punches in metal forming presses.

Support Plate

A plate that supports a draw ring or draw plate in a sheet metal forming press. It also serves as a spacer. See also *draw plate* and *draw ring*.

Supporting Electrode

An electrode, other than a self-electrode, on which the sample is supported during spectro-chemical analysis.

Surface Alterations (Metals)

Irregularities or changes on the surface of a material due to machining or grinding operations. The types of surface alterations

associated with metal removal practices include mechanical (e.g., plastic deformation, hardness variations, cracks, etc.), metallurgical (e.g., phase transformations, twinning, recrystallization, and untempered or overtempered martensite), chemical (e.g., intergranular attack, embrittlement, and pitting), thermal (heat-affected zone, recast, or redeposited metal, and resolidified material), and electrical surface alterations (conductivity change or resistive heating).

Surface Area

(1) The area, per unit weight of a granular or powdered solid, of all external and internal surfaces that are accessible to a penetrating gas or liquid. Surface area is given as square meters or kilogram (m^2/kg) or square centimeters per gram (cm^2/g). (2) The actual area of the surface of a casting or cavity. The surface area is always greater than the *projected area*.

Surface Checking

Same as *checks*.

Surface Contact Points

In powder metallurgy, the points at which abutting particles may contact during contacting and which grow into necks during sintering. See also *neck* and *neck formation*.

Surface Damage

In tribology, damage to a solid surface resulting from mechanical contact with another substance, surface, or surface moving relatively to it and involving the displacement or removal of material. In certain contexts, *wear* is a form of surface damage in which material is progressively removed. In another context, surface damage involves a deterioration of function of a solid surface even though there is no material loss from that surface. Surface damage may therefore precede wear.

Surface Diffusion

One of the primary diffusion mechanisms during sintering. It is predominant and for smaller particles and lower sintering temperatures as compared to other diffusion mechanisms, such as lattice or volume diffusion, which are prevalent for larger particles and higher temperatures. See also *volume diffusion*.

Surface Distress

In bearings and gears, damage to the contacting surfaces that occurs through intermittent solid contact involving some degree of sliding and/or surface fatigue. Surface distress can occur in numerous forms depending on the conditions under which the bearing or gear was operated and on the nature of the interaction between the contacting surfaces.

Surface Engineering

Matters concerning any aspect of surface condition or treatment encoding machining, peening, residual stress, polishing, plating, case hardening, diffusion treatment, conversion coatings, and key for painting.

Surface Effects

This term usually refers to the influence on fatigue properties of surface features such as polished, scratches, machining, pitting, local residual stresses, and fretting.

Surface Film

Any continuous contamination on the surface of a powder particle.

S

Surface Finish

(1) The geometric irregularities in the surface of a solid material. Measurement of surface finish shall not include inherent structural irregularities unless these are the characteristics being measured. (2) Condition of a surface as a result of a final treatment. (3) The form and quality of a surface. It may be defined in qualitative terms such as polished, or mill finished or, particularly in the case of machined surfaces, it may be measured quantitatively or semi-quantitatively. The semi-quantitative techniques compare the roughness of the surface in question with a series of standard machine surfaces, the comparison being made by eye and or by scratching with a fingernail. The quantitative techniques use instruments which measure the surface texture and profile by optical methods or by running a stylus over the surface and measuring the height and pitch of the undulations. The irregularities are rarely simple and the equipment integrates the various long and short range deviations to give a roughness figure in micro-meters, microns or micro-inches. See also *roughness*.

Surface Grinding

Producing a plain surface by grinding.

Surface Hardening

A generic term covering several processes applicable to a suitable ferrous alloy that produces, by quench hardening only, a surface layer that is harder or more wear resistant than the core. There is no significant alteration of the chemical composition of the surface layer. The processes commonly used are *carbonitriding*, *carburizing*, *induction hardening*, *flame hardening*, *nitriding*, and *nitrocarburizing*. See *case hardening*.

Surface Integrity (Metals)

A technology that involves the specification and manufacture of unimpaired or enhanced surfaces through the control of the many possible alterations produced in a surface layer during manufacture. Surface integrity is achieved by the proper selection and control of manufacturing processes and the ability to estimate their effects on the significant engineering properties of work materials. See also *surface alterations* (metals).

Surface Modification

The alteration of surface composition or structure by the use of energy or particle beams. Elements may be added to influence the surface characteristics of the substrate by the formation of alloys, metastable alloys or phases, or amorphous layers. Surface-modified layers are distinguished from conversion or coating layers by their greater similarity to metallurgical alloying versus chemically reacted, adhered, or physically bonded layers. However, surface structures are produced that differ significantly from those obtained by conventional metallurgical processes. This latter characteristic further distinguishes surface modification from other conventional processes, such as amalgamation or thermal diffusion. Two types of surface modification methods commonly employed are *ion implantation* and *laser surface processing*.

Surface Pigments (for Brick)

Brick has a long history of durability. Environmental issues such as energy consumption and waste disposal are increasing in importance, producing opportunities for brick usage to increase.

Facing brick need no rendering, painting, or regular maintenance. They look good year after year and often century after century with

no energy or product input. The brick can be recycled again and again, and at the end of their lives can be used as aggregate. Brick are the material of the future, and as demand for brick increases, so will demand for choice. The range of choices can be expanded by using surface pigments.

Compositions

Surface pigments can be classified into several groups. Pigment mixtures, which on firing develop their intrinsic color, fall into the largest category of stains. The second class includes pigments that react with the brick surface sand or grog to produce a specific shade of color. Usually, the iron in the surface layers of the clay is the critical factor. There are also colors that have been stabilized by a prior treatment. These are normally used where it is necessary to have the maximum volume of brick one uniform color.

Ferrous and ferric oxides are the source of a large number of colors ranging from very bright yellow through reds and maroons to blacks. The tone of the red surface colors depends on the firing temperature, the compound from which the oxide was formed, and the kiln atmosphere.

The presence of zinc or titanium compounds modifies the iron color in pigments and produces a range of buffs and yellows.

The spectral range of brown pigments is extremely wide, ranging in shade from cream to dark farmhouse brown.

Black pigments are mixtures of compounds of iron and manganese. Occasionally, cobalt oxide is added to intensify the blue-black quality of some surface stains.

Normally, gray pigments are produced by diluting selected black stains with inert and reactive fillers. The dominant tone of any black pigment is apparent when it is diluted, and some satisfactory blacks show undesirable tones when used diluted as grays.

Dry and Wet Applications

Dry

There are several methods of applying pigments in dry foam. Surface pigments are trickle-fed through a sieve and then brushed or lightly rolled into the brick surface. Surface effects are applied by vibrating the granules onto the column and rolling them into the surface.

For surface pigments or frits added to aggregates, the aggregate (a sand, grog, or other suitable material) is mixed with the pigment or frit at a predetermined ratio.

Wet

Surface pigments can be added to water-based suspensions and applied as a spray, slurry, or engobe. For spraying, a ratio of one part by weight of pigment to four parts by weight of water is generally acceptable.

This thorough wetting of the finally powdered pigment ensures a smooth suspension.

Surface Preparation. The operations necessary to produce a desired or specified surface condition.

Surface Preparation (Adhesives). Physical and/or chemical preparation of an adherend to make it suitable for adhesive bonding.

Surface Rolling. See *rolling*.

Surface Roughness. Fine irregularities in the *surface texture* of a material, usually including those resulting from the inherent action of the production process. Surface roughness is usually reported as the arithmetic roughness average, R_a , and is given in micrometers or microinches. See also the term *roughness*.

Surface Tension. (1) The force acting on the surface of a liquid, tending to minimize the area of the surface. (2) The force existing in a liquid-vapor phase interface that tends to diminish the area of the interface. This force acts at each point on the interface in the plane tangent to that point. (3) The phenomenon by virtue of which a liquid appears to have a skin and form a meniscus or stand as globules on a non-wetted surface. It arises from the mutual attraction between molecules exposed at the surface and the consequent tendency of a surface to contract to the smallest possible area.

Surface Texture. The roughness, waviness, lay, and flaws associated with a surface as defined by the term *roughness*. See also *lay*.

Surface Treatment. In composites fabrication, a material (size or finish) applied to a fibrous material during the forming operation or in subsequent processes. For carbon fiber surface treatment, the process used to enhance bonding capability of fiber to resin. See also *size*.

Surface Void. A void which is located at the surface of a material and is a consequence of processing, that is, a surface reaction layer, as distinguished from a volume distributed flaw such as a *pore* or *inclusion*.

Surfacing. (1) The deposition of filler metal (material) on a base metal (substrate) to obtain desired properties or dimensions. (2) The deposition of material, particularly by welding or similar processes, to provide a surface coating having properties such as high hardness or corrosion resistance is superior to the substrate. Where the intention is merely to restore dimensions, the term *Building-Up* is often considered more appropriate. See also *buttering*, *cladding*, *coating*, and *hard facing*.

Surfacing Mat. A very thin mat, usually 180–510 μm (7–10 mils) thick, of highly filamentized fiberglass, used primarily to produce a smooth surface on a reinforced plastic laminate, or for precise machining or grinding.

Surfacing Weld. A type of weld composed of one or more stringer or weave beads deposited on an unbroken surface to obtain desired properties or dimensions. See also *stringer bead* and *weave bead*.

Surfactant. (1) A chemical substance characterized by a strong tendency to form adsorbed interfacial films when in solution, emulsion, or suspension, thus producing effects such as low surface tension, penetration, boundary lubrication, wetting, and dispersing. (2) A compound that affects interfacial tension between two liquids. It usually reduces surface tension. See also *Rehbinder effect*.

Suspension. A liquid containing a solid material in finely divided particulate form and evenly dispersed rather than settled as a deposit.

Sustained Load Failure. Failure in steels usually high tensile, at stress levels that would normally be acceptable and possibly after a considerable period of time. It results from excessive hydrogen content and is accompanied by negligible ductility. See *hydrogen damage*.

Swabbing. Wiping of the surface of a metallographic specimen with a cotton ball saturated with etchant to remove reaction products simultaneously.

Swage. (1) The operation of reducing or changing the cross-section area of stock by the fast impact of revolving dies. (2) The tapering of bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper. See also the term *rotary swager*.

Swaging. (1) Reducing the diameter of bar, etc., by forging, hammering, or similar processes by hand or machine as in *rotary swaging*. (2) Tapering bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper. See also *rotary swaging*.

Swarf. (1) The strands of chippings of scrap material cut from components during machining operations such as drilling and turning. Also the sludge formed by grinding and comprising metal and grit. (2) Intimate mixture of grinding chips and fine particles of abrasive and bond resulting from a grinding operation.

Sweat. (1) Exudation of a low-melting phase during solidification of metals. Also known as *sweat-back*. For tin bronzes, it is called tin sweat. (2) Low melting point material exuding from the surface of castings during the final stages of solidification. See *segregation*. (3) Moisture condensing on cold components heated with a gas flame. See also *exudation*.

Sweating. (1) Exudation of bearing material or lubricant due to high temperature. (2) A soldering technique in which two or more parts are precoated (tinned), then reheated and joined without adding more solder. Also called *sweat soldering*.

Sweating Out. Bringing small globules of one of the low-melting constituents of an alloy to the surface during heat treatment, such as lead out of bronze.

Sweat Soldering. See *sweating* (2).

Sweep. A type of foundry pattern that is a template cut to the profile of the desired mold shape that, when revolved around a stake or spindle, produces that shape in the mold.

Swedish Iron. An imprecise term usually implying high purity iron, particularly one made from high-grade ores smelted with charcoal and refined to minimize contamination.

Sweeps. Sweepings, dust, and other debris collected from the floors and other surfaces of premises handling precious metals. It is collected for extraction of the valuable metal.

Sweep Velocity. The mean of the surface velocities of two bodies at the area of contact. Occasionally, the sum of the velocities is quoted instead of the mean. In rolling, the sweep velocity is also called the rolling velocity.

Sweet Roast. Same as *dead roast*.

S.W.G. Standard Wire Gauge.

Swift Cup Test. A stimulative test for determining formability of sheet metal in which circular blanks of various diameters are clamped in a die ring and deep drawn into a cup by a flat-bottomed cylindrical punch. The ratio of the largest blank diameter that can be drawn successfully to the cup diameter is known as the *limiting drawing ratio (LDR)* or *deformation limit*.

Swing Forging Machine. Equipment for continuously hot reducing ingots, blooms, or billets to square flats, rounds, or rectangles by the crank-driven oscillating action of paired dies.

Swing Frame Grinder. A grinding machine suspended by a chain at the center point so that it may be turned and swung in any direction for grinding of billets, large castings, or other heavy work. Principal use is removing surface imperfections and roughness.

S

S.W.L. Safe Working Load.

Symmetrical Laminate. A *laminate* in which the stacking sequence of plies below its midplane is a mirror image of the stacking sequence above the midplane.

Synchronous Initiation. In resistance welding, the initiation and termination of each half-cycle of welding transformer primary current so that all half-cycles of such current are identical in making spot and seam welds or in making projection welds.

Synchronous Timing. See preferred term *synchronous initiation*.

Synchrotron. A device for accelerating charged particles by directing them along a roughly circular path in a magnetic guide field. As the particles pass through accelerating cavities placed along their orbits, their kinetic energy is increased repetitively, multiplying their initial energy by factors of hundreds or thousands. See also *synchrotron radiation*.

Synchrotron Radiation. Electromagnetic radiation emitted by charged particles in circular motion at relativistic energies.

Syndiotactic Stereoisomerism. A polymer molecule in which side atoms or side groups alternate regularly on opposite sides of the chain. See the term *isotactic stereoisomerism*.

Syneresis (of a Grease). See *bleeding* (2).

Syneresis. Spontaneous separation of a liquid from a gel due to contraction of the gel.

Syntactic Cellular Plastics. Reinforced plastics made by mixing hollow microspheres of glass, epoxy, phenolic, and so forth, into fluid resins (with additives and curing agents) to form a moldable, curable, lightweight, fluid mass; as opposed to foamed plastic, in which the cells are formed by gaseous bubbles released in the liquid plastic by either chemical or mechanical action. Also known as *syntactic foams*.

Syntectic. An isothermal reversible reaction in which a solid phase, on absorption of heat, is converted to two conjugate liquid phases.

Syntectic Equilibrium. A reversible univariant transformation in which a solid phase that is stable only at lower temperature decomposes into two conjugate liquid phases that remain stable at higher temperature.

Synthetic Cold Rolled Sheet. A hot rolled pickled sheet given a sufficient final temper pass to impart a surface approximating that of cold rolled steel.

Synthetic Natural Rubber (Isoprene)

Stereo regular polyisoprene and polybutadiene elastomers, high in *cis*-1,4 content, are of growing interest to the engineer, both because of engineering performance, and their competitive price. IR (*cis*-polyisoprene) has been called "synthetic natural rubber" because chemically and physically it is similar to *Hevea*.

General properties and examples of end-use performance show it to be a satisfactory supplement to natural rubber in a wide

variety of products. Molecular weight can be controlled within quite wide limits and linearity can be maintained even with the longest chains. Higher-molecular-weight materials have been satisfactorily extended with oil to yield compositions with a desirable combination of low cost and attractive properties.

The development of IR latex is a noteworthy advance in latex technology. The low emulsifier level, stereoregularity of the polymer, large particle size, and low viscosity have not hitherto been available in a general-purpose synthetic latex. These properties, combined with high gum strength and elongation, offered advantages for many latex applications.

Vulcanizate Properties

IR can be processed in a manner similar to that used for natural rubber. Vulcanization can be carried out by means of curatives commonly used with natural or SBR. Properties of gum vulcanizates are quite similar to those of natural rubber, although IR has somewhat lower modulus and higher extensibility.

There are excellent hysteresis properties, low heat buildup and high resilience of both the IR and the polybutadiene tread vulcanizates, and IR is second only to natural rubber and tear strength.

Processing and compounding procedures for oil-extended IR are similar to those for an extended polymer, except that lower curative levels are recommended for maximum tensile strength and flat curing characteristics. Properties of extended vulcanizates approach those of the non-extended materials.

Applications

Similarity of performance between IR and natural rubber has permitted use of IR as a supplement for natural rubber in uses such as tire treads, carcasses, and white sidewalls.

In nontire uses the low ash content, light color, and good mold flow characteristics of IR are of particular advantage. Good electrical properties and low moisture absorption make it suitable for a number of electrical insulating uses. Parts molded in IR exhibit sharp definition and excellent color stability to light.

The low cost and good performance of oil-extended IR are promising for tire carcass compounds, molded mechanical goods, and footwear.

In latex form, IR is the first synthetic that possesses an average particle size as large and a particle size distribution as broad as that of natural rubber latex. It is highly promising for a number of coating and dipping applications, as well as foaming.

Synthetic Oil

Oil produced from chemical synthesis rather than from petroleum. Examples are esters, ethers, silicons, silanes, and halogenated hydrocarbons.

Système International d'Unités

The International System of Units adopted by the General Conference of Weights and Measures and endorsed by the International Organization for Standardization. See *S.I. System*.

T_g

See *glass transition temperature*.

T Joint

A joint between the end or age of one component and the face of another. Some usage of the term is confined to joints where the two components are at approximately right angles but other usage includes joints where the angle is much more acute and the weld is a fillet.

T.T.T. Curves

Time, temperature, transformation curves. See *isothermal transformation curves*.

Tabs

Extra lengths of reinforced plastic or other material at the ends of the tensile specimen to promote failure away from the grips. Also called doublers.

Tack

That property of an adhesive that enables it to form a bond of measurable strength immediately after adhesive and adherend are brought into contact under low pressure. See also *dry tack*, *tack range*, and *tacky dry*.

Tack Range

The period of time in which an adhesive will remain in the *tacky dry* condition after application to the adherend, under specified conditions of temperature and humidity.

Tack Welds

(1) Small, scattered welds made to hold parts of a weldment in proper alignment, while the final welds are being made. (2) Intermittent welds to secure weld backing bars. See also *backing* (2).

Tacking

Making *tack welds*.

Tacky Dry

The condition of an adhesive when the volatile constituents have evaporated or been absorbed sufficiently to leave it in a desired tacky state.

Taconite

A siliceous iron formation from which certain iron ores of the Lake Superior region are derived; consists chiefly of fine-grain silica mixed with magnetite and hematite.

Tafel Line, Tafel Slope, Tafel Diagram

When an electrode is polarized, it frequently will yield a current/potential relationship over a region that can be approximated by $\eta = \pm \beta \log(i/i_0)$, where η is the change in open-circuit potential, i is the current density, and β and i_0 are constants. The constant β is also known as the Tafel slope. If this behavior is observed, a plot on semilogarithmic coordinates is known as the Tafel line and the overall diagram is termed a Tafel diagram.

Tagging

Reducing the diameter of the end of a bar to allow its insertion through a drawing die or into a swaging machine.

Tailings

The material left after a low-grade ore has been concentrated. It will contain some of the desired metal but not in economically recoverable quantities.

Talc

Talc is a hydrous magnesium silicate with the composition 63.4% SiO_2 , 31.9% MgO , and 4.7% H_2O when found in pure form. It is an extremely soft mineral with a Mohs hardness of 1.

Talc is a soft friable mineral of fine colloidal particles with a soapy feel. It has a composition of $4\text{SiO}_2 \cdot 3\text{MgO} \cdot \text{H}_2\text{O}$ and a specific gravity of 2.8. It is white whelf pure, but may be colored gray, green, brown, or red with impurities.

Talc is now used for cosmetics, for paper coatings, as a filler for paints and plastics, and for molding into electrical insulators, heater parts, and chemical ware. The massive block material, called steatite talc, is cut into electrical insulators. It is also called lava talc. The more impure block talcs are used for firebox linings and will withstand temperatures to 927°C . Gritty varieties contain carbonate minerals and are in the class of soapstones. Varieties containing lime are used for making porcelain.

Talc used in ceramics is usually mined, sorted, crushed, and milled to 95%–99%—200 mesh.

Talc is also termed soapstone or steatite and has a characteristic soapy or greasy feel. Used as an ingredient in ceramic whiteware and ceramic wall and floor tiles.

Cordierite is a talc-like mineral with a high percentage of magnesia used for refractory electronic parts. Extruded cordierite serves as a substrate for the active catalyst metals in auto catalytic converters.

T

Magnesium silicate, used as a filler in rubber and plastics and also as an alkaline bleaching agent for oils, waxes, and solvents, is a white, water-insoluble powder of composition MgSiO_4 , having a pH of 7.5–8.5. In the cosmetic trade, it is known as talcum powder.

Applications

The major applications for talc are tile and hobbyware bodies, cordierite catalyst supports, kiln furniture, and electrical porcelains. There are minor applications in electronic packaging, sanitary ware, dinnerware, and glazes.

Talc is used as a flux for high alumina ceramics, sanitary ware, and dinnerware. It is a low-cost source of magnesium in these applications and helps to produce less porous bodies at lower firing temperatures. It is readily carved for ornamental applications. In powdered form, it is termed French chalk or, if perfumed, talcum powder.

Tall Oil

An orderly, resinous liquid obtained as a by-product of the sulfite paper-pulp mills. The alkali saponifies the acids, and the resulting soap is skimmed off and treated with sulfuric acid to produce tall oil. The name comes from the Swedish *talloel*, meaning pine oil. The crude oil is brown, and the refined oil is reddish yellow and nearly odorless. It has a specific gravity of 0.98. The oil from Florida paper mills contains 41%–45% rosin, 10%–15% pitch, and the balance chiefly fatty acids. The fatty acids can be obtained separately by fractionating the crude whole oil. The oil also contains up to 10% of the phytosterol *sitosterol*, used in making the drug cortisone.

Tall oil is used in scouring soaps, asphalt emulsions, cutting oils, insecticides, animal dips, in making factice, and in plastics and paint oils. It is marketed in processed and concentrated form.

Tallow

A general name for the heavy fats is obtained from all parts of the bodies of sheep and cattle. The best grades of internal fats, or *suets*, are used for edible purposes, but the external fats are employed for lubricants, for mixing with waxes and vegetable fats, for soaps and candles, and for producing chemicals. The tallows have the same general composition as lard but are higher in the harder saturated acids, with about 51% of palmitic and stearic acids, and lower in oleic acid. The edible grades known as *premier jus*, prime, and edible are white to pale yellow, almost tasteless, and free from disagreeable odor, but the nonedible or industrial tallows are yellow to brown unless bleached. The best grade of industrial tallow is Packers No. 1. *Peacock* is in acidless grade for metal working, lubricants and additives, soaps, mold release, animal feed supplements, inks, and pigments; other premium and custom grades of Peacock are also produced by George Pfau's Co.

Talysurf

See *surface finish*.

Tamp

To form or compact a ceramic mixture or a particulate solid by tamping or repeated impact, usually performed manually.

Tan Delta (Tan δ)

(1) The ratio of the loss modulus to the *storage modulus*, measured in compression, *K*; tension or flexure, *E*; or shear, *G*. See also *complex modulus* and *loss modulus*. (2) The ratio of the out-of-phase components of the dielectric constant (i.e., the loss) to the in-phase component of the dielectric constant (i.e., the permittivity). See also *loss factor*.

Tandem Die

Same as *follow die*.

Tandem Mill

A rolling mill consisting of two or more stands arranged so that the metal being processed travels in a straight line from stand to stand. In continuous rolling, the various stands are synchronized so that the strip can be rolled in all stands simultaneously. The rotational speeds of the individual stands are correlated to maintain a steady movement of the product without interstage kinking or excessive tension. In contrast with *single-stand mill*. See also *rolling mills*.

Tandem Seal

A multiple-seal arrangement consisting of two seals mounted one after the other, with the faces of the seal heads oriented in the same direction.

Tandem Welding

Arc welding in which two or more electrodes are in a plane parallel to the line of travel.

Tangent Bending

The forming of one or more identical bands having parallel axes by wiping sheet metal around one or more radius dies in a single operation. The sheet, which may have side flanges, is clamped against the radius die and then made to conform to the radius die by pressure from a rocker-plate die that moves along the periphery of the radius die. See also *wiper forming* (*wiping*).

Tangent Modulus

(1) The elastic modulus measured over a small change in stress. It is relevant for those cases where stress is not proportional to strain so the stress–strain line in the elastic range is a curve rather than a straight line. As the term indicates, it is measured as the tangent to the line at the stress of interest. (2) The slope of the *stress–strain curve* at any specified stress or strain. See also *modulus of elasticity* and see *tensile test*.

Tangential Stress

See *shear stress*.

Tank Voltage

The total voltage between the anode and cathode of a plating bath or electrolytic cell during electrolysis. It is equal to the sum of (a) the equilibrium reaction potential, (b) the *IR* drop, and (c) the electrode potentials.

Tanning Agents

Materials, known as *tannins*, used for the treatment of skins and hides to preserve the hide substance and make it resistant to decay. The tanned leather is then treated with fats or greases to make it soft and pliable. Tannins may be natural or artificial. The natural tannins are chiefly vegetable, but some mineral tanning agents are used. The vegetable tannins are divided into two color classes: the *catechol* and the *pyrogallol*. The catechol tannins are cutch, quebracho, hemlock, larch, gambier, oak, and willow. The pyrogallol tannins are gallnuts, sumac, myrobalans, chestnut, valonia, divi-divi, and algarobilla.

In the ink industry, the catechol tannins are known as *iron green*, and the pyrogallol tannins as *iron bluing*, and the latter are used for making writing inks. Catechol is also produced synthetically from coal tar. It is a water-soluble *dihydric phenol* and is used in some inks and for making dyestuffs, medicinals, and antioxidants.

Alum tanning is an ancient process but was introduced in Europe only about the year 1100, and the alum- and salt-tanned leather was called *Hungary leather*. *Formaldehyde* is also used as a tanning agent. Formaldehyde was patented as a tanning agent in 1898. A later patent covered a rapid process of tanning sheepskins with alcohol and formalin and then neutralizing in a solution of soda ash. Unlike vegetable agents, formaldehyde does not add weight to the skin. It is often used as a pretanning agent to lessen the astringency of the vegetable tannins and increase its rate of diffusion. *Melamine* resins are used for tanning to give a leather that is white throughout and does not yellow with age. Leather may also be tanned with chromic acid or chrome salts, which make the fibers insoluble and produce a soft, strong leather. Chrome alum, sodium or potassium dichromates, or products in which chromic acid has been used as an oxidizing agent may be used. *Chrome tanning* is rapid and is used chiefly for light leathers.

Tantalum and Alloys

Tantalum is a white lustrous metal (symbol Ta), resembling platinum. Tantalum is a high-density, ductile, refractory metal that exhibits exceptional corrosion resistance and good high-temperature strength over 1663°C. The annealed wrought metal in its pure form is easily worked and can be cold worked in much the same manner as fully annealed mild steel.

It is one of the most acid-resistant metals and is classed as a noble metal. Its specific gravity is 16.6, or about twice that of steel and, because of its high melting temperature (2996°C), it is called a refractory metal. In sheet form, it has a tensile yield strength of 345 MPa and is quite ductile. At very high temperatures, however, it absorbs oxygen, hydrogen, and nitrogen and becomes brittle. Its principal use is for electrolytic capacitors, but because of its resistance to many acids, including hydrochloric, nitric, and sulfuric, it is also widely used for chemical-processing equipment. It is attacked, however, by hydrofluoric acid, halogen gases at elevated temperatures, fuming sulfuric acid, and strong alkalis. Because of its heat resistance, tantalum is also used for heat shields, heating elements, vacuum-furnace parts, and special aerospace and nuclear applications. It is a common alloying element in superalloys. The metal is also used for prosthetic applications.

Tantalum metal is used in the manufacture of capacitors for electronic equipment, including citizen band radios, smoke detectors, heart pacemakers, and automobiles. An extremely stable film of tantalum oxide acts as an insulator in the capacitor. It is also used for heat-transfer surfaces in chemical production equipment, especially where extraordinarily corrosive conditions exist. Its chemical inertness has led to dental and surgical applications.

Tantalum forms alloys with a large number of metals. Of special importance is ferrotantalum, which is added to austenitic steels to reduce intergranular corrosion. Tantalum is used extensively in the chemical industry where its excellent fabrication and joining properties permit the application to acid-resistant heat exchangers, condensers, ductwork, chemical lines, and other chemical process equipment. Tantalum also finds use in the medical profession. Because of its nontoxic properties and immunity to body chemicals, tantalum is used for sutures, gauze, pins, and plates.

Fabricability

Hot Working

High-purity tantalum sintered bar, cast ingot, and annealed wrought forms can be worked at room temperature, although the working of large ingots and billets is sometimes performed at elevated temperature to permit working within equipment strength capacity. Cast ingots, protected by canning or coating materials, have been forged and extruded at temperatures up to 1316°C. Cold-work tantalum can be stress relieved or annealed at a variety of time-temperature schedules depending upon stress level and chemical purity of the material. A temperature of at least 1204°C is generally used for full annealing, while temperatures between 816°C and 927°C can be used for stress relieving. Annealing atmosphere must be high-purity argon, helium, or, preferably, a vacuum of 1/10 of a micron or less.

Cold Working

The excellent room-temperature ductility of stress-relieved and fully annealed tantalum makes the forming of tantalum comparatively simple. But the grain size of the material must be carefully considered for requirements where surface finish is of importance. The combination of a higher tensile strength and fair uniform elongation of stress-relieved tantalum sometimes makes it more satisfactory for drawing and forming than fully annealed material. It is very important to consider the temper properties of the material in the design of forming tools.

Joining

Tantalum can be joined by electron beam, tungsten-inert gas, and spot and resistance welding, but must be carefully protected from the effects of oxidation during welding. Uncontaminated welds are ductile and usually can be worked at room temperature.

Electron-beam-melted 90% tantalum–10% tungsten alloy can be formed and joined in a similar manner as pure tantalum provided that the higher strength and more rapid work-hardening characteristics of the alloy are considered.

Alloys

Tantalum alloys, including tungsten and tungsten–hafnium compositions, such as Ta-10W, T-111 (8% tungsten, 2% hafnium), and T-222 (9.6% tungsten, 2.4% hafnium, and 0.01% carbon), are used for rocket-engine parts and special aerospace applications. The tensile yield strength of Ta-10W is about 1089 MPa at room temperature and 621 MPa and 871°C.

Tantalum Beryllides and Carbides

Tantalum Beryllide

TaBe₁₂ and TaBe₁₇ are intermetallic compounds with good strength at elevated temperatures. TaBe₁₂ is tetragonal; density is 4.18 g/cm³; melting point is 1849°C; and coefficient of thermal

T

expansion is $8.42 \times 10^{-6}/^{\circ}\text{C}$. TaBe_{17} is hexagonal; density is 5.05 g/cm^3 ; melting point is 2045°C ; and coefficient of thermal expansion is $8.72 \times 10^{-6}/^{\circ}\text{C}$. Both compounds can be formed by all of the known ceramic-forming methods plus flame and plasma-arc spraying. The materials are subject to safety requirements for all beryllium compounds.

Tantalum Carbide

TaC and Ta_2C are the two primary carbides. The ore tantalum carbide with a congruent melting point is TaC . It is dark to light brown in color with a metallic luster. Ta_2C melts in congruently and is gray with a metallic luster. Ta_2C melts at 3400°C ; the melting point of TaC has been reported to be as high as 4820°C .

TaC burns in air with a bright flash and is only slightly soluble in acids. The tensile strength at room temperature is 13.6–27.2 MPa.

Tantalum carbide is used in cemented carbide-cutting tools.

Tap

A cylindrical or conical thread-cutting tool with one or more cutting elements having threads of a desired form on the periphery. By a combination of rotary and axial motions, the leading end cuts an internal thread, the tool deriving its principal support from the thread being produced. The tool is used for cutting threads on the surface of a whole.

Tap Density

The apparent density of a powder, obtained when the volume receptacle is tapped or vibrated during loading under specified conditions.

Tape

In composites manufacture, a unidirectional *prepreg* that consists of a thin sheet of fiber reinforced uncured resin usually wound on a cardboard core.

Tape Casting

Tape casting is a familiar technique to most ceramic engineers. It has been widely used as a method for fabricating improved capacitors. Conceptually, the process is simple. First, a slurry is prepared that contain ceramic powder (or powders) suspended in a solution of polymers. The slurry is read into a relatively thin liquid coating on a smooth surface. The solution is then removed, usually through evaporation, although absorption into a porous medium can also be used, and a dry film is formed that is a green ceramic powder compact, termed *green sheet*.

The tape usually has three qualitatively distinct phases: an inorganic powder, a continuous polymer–matrix, and a porosity phase. (The powder is dispersed within the polymer–matrix.) Each phase is important. In considering each of these phases, it is useful to recognize that the process to produce green sheet is usually best regarded as a primary process, and one or more secondary operations are necessary to complete the fabrication of a green part ready for firing.

Applications

The “classic” applications of tape casting are centered in the electronics industry and include the production of flat, smooth substrates

for either thick film or integrated circuitry, capacitors, dielectrics, and piezoelectric elements.

Layered Manufacturing

Although the ability to mix materials and stack sheets has long been recognized in the electronics industry, a recent and important development has been the recognition that green sheet can play an important role as a feedstock for rapid prototyping (RP), also known as solid freeform fabrication. Although much that is useful can be derived from the work done for electronic applications, there are a number of distinct requirements for RP that produce additional constraints on green-sheet physical properties and, therefore, formulations.

The field of RP was developed in response to the high cost of tooling that is often an obstacle to implementing design changes or material substitution. All RP processes start with a computer-aided design, computationally approximated by a series of closely spaced 2D outlines, then use a process to construct each outline sequentially, assemble them, and suitably postprocess the assemblage to yield the final part.

Frequently, the term “layered manufacturing” is also applied to these processes. This name is particularly appropriate since each process involves the fabrication of a 3D object by automatic sequential stacking of appropriately contoured thin (pseudo-2D) sections. By controlling *x*–*y* motions in each layer, an (in principle) arbitrary component can be built up.

Each RP technology is distinguished by the process and machinery used to define each thin section and create the final stack.

RP and Ceramics

The application of solid freeform fabrication to engineering ceramics is motivated by a desire to take advantage of the striking advances in these materials over the last 20 years (such as transformation-toughened oxides, high-toughness silicon nitrides, and ceramic-matrix composites) as a result of government-funded research programs throughout the world.

CAM-LEM

The computer-aided manufacturing of laminated engineering materials (CAM-LEM) process was developed specifically for production of ceramic parts.

Among the ceramic formulations that have been used with CAM-LEM are alumina, silicon nitride, zirconia-toughened oxides, and PZT.

The essence of the CAM-LEM process includes feeding the green sheet onto a movable platform, creating a cut outline through relative motion of the table and laser, automatic and selective extraction of the cut outline, and addition to the build start. Conversion to a dense ceramic article requires lamination of the green sheets followed by binder burnout and firing.

The total time to produce a ceramic part is the sum of that required to produce the green part plus the firing time, which includes binder burnout and sintering. The CAM-LEM process produces green parts that are compatible with conventional firing cycles for laminated tape-cast parts.

Tape Replica Method (Faxfilm)

A method of producing a *replica* by pressing the softened surface of tape or plastic sheet material onto the surface to be replicated.

Tape Wrapped

In composites fabrication, wrapping of heated fabric tape onto a rotating mandrel, which is subsequently cooled to form the surface for the next tape player application.

Taper Section

A section cut obliquely (acute angle) through a surface and prepared metallographically. The angle is often chosen to increase the vertical magnification of surface features by a factor of 5 or 10. Taper sectioning is usually carried out for microstructural examination of coated metal specimens.

Tapered Land Bearing

A *thrust bearing* containing pads of fixed taper.

Tapered Roller Bearing

A *rolling-element bearing* containing tapered rollers.

Tapping

(1) Producing internal threads with a cylindrical cutting tool having two or more peripheral cutting elements shaped to cut threads of the desired size and form. By a combination of rotary and axial motion, the leading end of the tap cuts the thread, while the tap is supported mainly by the thread it produces. See *tap*. (2) Opening the outlet of a melting furnace to remove molten metal. (3) Removing molten metal from a furnace.

Tar

A black, solid mass obtained in the destructive distillation of coal, peat, wood, petroleum, or other organic material. When coal is heated to redness in an enclosed oven, it yields volatile products and the residue coke. Upon cooling, the volatile matter, tar, and water are deposited, leaving the coal gases free. Various types of coal yield tars of different qualities and quantities, depending on the relative levels of more than 200 compounds, including *guaiacol*, *cresol*, *xyleneol*, *crotonic acid*, *maltol*, and *ketones*. Anthracite gives little tar, and cannel coal yields large quantities of low-gravity tar. In the manufacture of gas, the tar produced from bituminous coal is a viscous, black liquid containing 20%–30% free carbon and is rich in benzene, toluene, naphthalene, and other aromatic compounds. In the dry state, this tar has a specific gravity of about 1.20. Tar is also produced as a by-product from coke ovens.

Coal tars are usually distilled to remove the light aromatics, which are used for making chemicals, and the residue tar, known as *treated tar*, or *pitch*, is employed for roofing, road making, and bituminous paints and waterproofing compounds. *Coal-tar pitch* is the most stable bituminous material for covering underground pipes, as a binder for electrodes used in aluminum smelting, and as an impregnant in refractories. *Coal-tar carbon* amounts to about 32% of the original tar. It is marketed in lump form for chemical use. The fixed carbon content is 92.5%–95.6%, sulfur about 0.30, and volatile matter 3–6. *Calcined carbon*, from coal tar, contains less than 0.5% sulfur and 0.5% volatile matter.

The lightest distillate of coal tar, benzene, is used as an automotive fuel. *Coal-tar oils* are used as solvents and plasticizers.

They consist of various distillates or fractions up to semisolids. *Tar oil* from brown coal tars was used for diesel fuel oil by extracting the phenols with methyl alcohol.

Pine tar is a by-product in the distillation of pinewood. It is a viscous, black mass and is much used for roofing. *Rosintene* is a light grade and is also sometimes called pitch, but pitch is the tar with the pine-tar oil removed, known as *pine pitch*. Navy pitch and ship pitch are names that refer to specification pine pitch for marine use. It is medium hard to solid; has a specific gravity of 1.08–1.10, as a melting point not less than 64°C; is completely soluble in benzol; and has uniform black color or red–brown in thin layers. *Wood tar* from the destructive distillation of other woods is a dark-brown, viscous liquid used as a preservative, deriving this property from its content of creosote.

Target

That part of an x-ray tube in an x-ray spectrometer, which the electrons strike and from which x-rays are emitted.

Tarnish

Surface discoloration of a metal caused by formation of a thin film of corrosion product.

Taylor Process

A process for making extremely fine metal wire by inserting a piece of larger-diameter wire into a glass tube and stretching the two together at high temperature. The wire may be coated when inserted into the glass tube or by being drawn through a small bath of molten glass.

Taylor Vortices

In a *journal bearing*, vortices formed in a liquid occupying the annular space between two concentric cylinders.

TD Nickel

Nickel that is dispersion strengthened by thoria (thorium oxide).

TEM

Transmission electron microscope. See *electron microscope*.

Teapot Ladle

A ladle in which, by means of an external spout, metal is removed from the bottom rather than the top of the ladle. See *ladle*.

Technetium

A metallic element having little commercial application.

Technical Ceramics

Same as *advanced ceramics*.

T

Technical Glass

A term that usually refers to glasses designed with some specific property essential for a mechanical, industrial, or scientific device.

Tee Joint

A joint in which the members are oriented in the form of a T.

Teeming

Pouring molten metal from a ladle into ingot molds. The term applies particularly to the specific operation of pouring either iron or steel into ingot molds.

Teeming Line/Height

The level in an ingot mold to which the molten metal was initially poured.

Teeth

The resultant surface irregularities or projections formed by the breaking of filaments or strings, which may form when adhesive-bonded substrates are separated. See also *legging*, *stringiness*, and *webbing*.

Telegraphing

In a laminate or other type of composite construction, a condition in which irregularities, imperfections, or patterns of an inner layer are visibly transmitted to the surface. Telegraphing is occasionally referred to as photographing.

Tellurium

An elementary metal (symbol Te) tellurium is obtained as a steel-gray powder of 99% purity by the reduction of tellurium oxide, or tellurite, TeO_2 . The specific gravity is about 6.2 and the melting point is 450°C . The chief uses are in lead to harden and toughen the metal and in rubber as an accelerator and toughener. Less than 0.1% tellurium in lead makes the metal more resistant to corrosion and acids and gives a finer grain structure and higher endurance limit. Tellurium-lead pipe, with less than 0.1% tellurium, has a 75% greater resistance to hydraulic pressure than plain lead. Tellurium copper (C14500, C14510, and C14520) is a free-machining copper containing 0.3%–0.7% tellurium. It machines 25% more easily than free-cutting brass. The tensile strength, annealed, is 206 MPa, and the electric conductivity is 98% that of copper. A tellurium bronze containing 1% tellurium and 1.5% tin has a tensile strength, annealed, of 275 MPa and is free-machining. Tellurium is used in small amounts in some steels to make them free-machining without making the steel hot short as do increased amounts of sulfur. But tellurium is objectionable for this purpose because inhalation of dust or fumes by workers causes garlic breath for days after exposure, although the material is not toxic. As a secondary vulcanizing agent with sulfur in rubber, tellurium in very small proportions, 0.5%–1%, increases the tensile strength and aging qualities of the rubber. It is not as strong an accelerator as selenium, but it gives greater heat resistance to the rubber.

Tellurium is an important component of many thermoelectric devices, and such devices can be used for both power generation and cooling. The requirements of a good thermoelectric element are

high thermoelectric power, low thermal conductivity, and low electrical resistivity. Lead telluride (PbTe), bismuth telluride (Bi_2Te_3), and silver antimony telluride meet these requirements better than any other currently known materials. By the addition of various other elements these compounds can be made either *p*-type or *n*-type semiconductors.

Oxides

The oxides of tellurium are tellurium monoxide, TeO ; tellurium dioxide, TeO_2 ; and tellurium trioxide, TeO_3 . The monoxide is reported as a black, amorphous powder that is stable in dry air in the cold but that is oxidized in moist air to the dioxide. On being heated in vacuum, it apparently disproportionates into the dioxide and elemental tellurium. It can be formed by heating the mixed oxide TeSO_3 . The dioxide is the most stable oxide and is formed when tellurium is burned in air or oxygen or by oxidation of tellurium with cold nitric acid. It has two crystalline forms.

Telomer

A polymer composed of molecules having terminal groups incapable of reacting with additional monomers, under the conditions of the synthesis, to form larger polymer molecules of the same chemical type. See also *monomer* and *polymer*.

Temper

(1) In steels it refers to

(1a) Reheating steel, previously hardened by heat treatment, and the range of 100°C – 700°C . This alters the microstructure, reduces hardness and strength but increases ductility and toughness. This is the most widely accepted meaning among metallurgists.

(1b) Carbon content.

Temper

(2) In many metals, but not usually steels, the various strength ranges are referred to as tempers. For example, aluminum has temper designations such as T4 or T6 with the higher number having higher strength. Also terms such as half hard, quarter hard, and full temper are termed tempers or temper grades.

Temper (Ceramics)

To moisten and mix clay, plaster, or mortar to proper consistency.

Temper (Glass)

(1) The degree of residual stress in annealed glass measured polarimetrically or by polariscopic comparison with a reference standard.
(2) Term sometimes employed in referring to *tempered glass*.

Temper (Metals)

(1) In heat treatment, reheating hardened steel or hardened cast iron to some temperature below the eutectoid temperature for the purpose of decreasing hardness and increasing toughness. The process also is sometimes applied to normalized steel. (2) In tool steels, temper is sometimes used, but inadvisably, to denote the carbon content.

(3) In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction in area during cold working. (4) To moisten *green sand* for casting molds with water.

Temper Brittleness

Reduced impact strength and low-fracture toughness of some martensitic or bainitic steels after heating into or cooling through the 300°C–600°C range. Fracture is intergranular and probably arises as a result of segregation of impurity elements such as arsenic, antimony, phosphorus, and tin to the prior austenite grain boundaries. See *temper embrittlement*.

Temper Carbon

Clusters of finally divided graphite, such as that found in malleable iron, that are formed as a result of the composition of cementite, for example, by heating white cast iron above the ferrite–austenite transformation temperature and holding at these temperatures for a considerable period of time. Also known as annealing carbon. See also *malleable iron*.

Temper Color

A thin, tightly adhering oxide skin (only a few molecules thick) that forms when steel is tempered at a low temperature, or for a short time, in air or a mildly oxidizing atmosphere. The color, which ranges from straw to blue depending on the thickness of the oxide skin, varies with both tempering time and temperature and provides a guide to the metal temperature.

Temper Embrittlement

Embrittlement of low-alloy steels caused by holding within or cooling slowly through a temperature range (generally 300°C–600°C), just below the transformation range. Embrittlement is the result of the segregation at grain boundaries of impurities such as arsenic, antimony, phosphorus, and tin; it is usually manifested as an upward shift in ductile-to-brittle transition temperature. Temper embrittlement can be reversed by retempering above the critical temperature range, then cooling rapidly. Compare with *tempered martensite embrittlement*.

Temper Hardening

- (1) Artificial aging as a part of a precipitation hardening process.
- (2) Secondary hardening.

Temper Rolling

Light cold rolling of sheet steel to improve flatness, to minimize the formation of *stretcher strains*, and to obtain a specified hardness or temper.

Temper Time

In resistance welding, that part of the postweld interval during which the current is suitable for tempering or heat treatment.

Temperature Coefficient of Resistance

The amount of resistance change of a material per degree of temperature rise.

Temperature Stress

The maximum stress that can be applied to a material at a given temperature without physical deformation.

Tempered Glass

Glass that has been subjected to a thermal treatment characterized by rapid cooling to produce a compressively stressed surface layer. See *safety glass*.

Tempered Layer

A surface or subsurface layer and a steel specimen that has been tempered by heating during some stage of the metallographic preparation sequence (usually grinding). When observed in a section after etching, the layer appears darker than the base material.

Tempered Martensite

The decomposition products that result from heating martensite before the ferrite–austenite transformation temperature. Under the optical microscope, darkening of the martensite needles is observed in the initial stages of tempering. Prolonged tempering at high temperatures produces spheroidized carbides in a matrix of ferrite. At the higher resolution of the electron microscope, the initial stage of tempering is observed to result in a structure containing a precipitate of fine iron carbide particles. At approximately 260°C, a transition occurs to a structure of larger and elongated cementite particles in a ferrite matrix. With further tempering at higher temperatures, the cementite particles become spheroidal, decreased in number, and increased in size.

Tempered Martensite Embrittlement

Embrittlement of high-strength alloy steels caused by tempering in the temperature range of 205°C–370°C; also called 350°C embrittlement. Tempered martensite embrittlement is thought to result from the combined effects of cementite precipitation on prior-austenite grain boundaries or interlath boundaries and the segregation of impurities at prior-austenite grain boundaries. It differs from *temper embrittlement* in the strength of the material and the temperature exposure range. In temper embrittlement, the steel is usually tempered at a relatively high temperature, producing lower strength and hardness, and embrittlement occurs upon slow cooling after tempering and during service at temperatures within the embrittlement range. In tempered martensite embrittlement, the steel is tempered within the embrittlement range, and service exposure is usually at room temperature.

Tempering

See *temper 1a* and *1b*.

Tempering (Glass)

The process of rapidly cooling glass from near its softening point to induce compressive stresses on the surface balanced by interior tension, thereby imparting increased strength.

T

Tempering (Metals)

In heat treatment, reheating hardened steel to some temperature below the eutectoid temperature to decrease hardness and/or increase toughness.

Tempilstiks

A proprietary brand of crayon available in a wide range of melting points. The component is marked with one or more crayons and observed during, or examined after processing or testing, to determine the temperature reached.

Template (Templet)

(1) A guide or a pattern in manufacturing items. (2) A gauge or pattern made in a die department, usually from sheet steel; used to check dimensions on forgings and as an aid in sinking *die impressions* in order to correct dimensions. (3) A pattern used as a guide for cutting and laying plies of a *laminate*.

Temporary Weld

A weld made to attach a piece or pieces to a weldment for temporary use and handling, shipping, or working on the weldment.

Tenacity

The term generally used in yarn manufacture and textile engineering to denote the strength of a yarn or of a filament of a given size. Numerically, it is the grams of breaking force per denier unit of yarn or filament size. Grams per denier is expressed as gpd. See also *denier* and *tensile strength*.

Tensile Modulus

Stress is defined as the force per unit area and is calculated by dividing the applied load by the original cross section to the test piece. The SI unit of stress is the pascal (P), or more practical, megapascal (MPa); typical imperial units are tons per square inch (t/in.²) or, particularly in the United States, pounds per square inch (psi) or thousands of pounds per square inch (tpsi). Non-SI-metricated units include kilograms per square millimeter (kg/mm²) and newtons per square millimeter (N/mm²). The extension is the total amount by which the gauge length of the test piece is stretched. Strain is defined as the extension per unit length and is calculated by dividing the extension by the original gauge length. It is usually expressed as a percentage although terms such as inches per inch may be used.

For most tensile tests, it is conventional to plot a graph of stress against strain, often referred to as a stress/strain curve, to allow calculation of mechanical properties. As the load is increased progressively during a typical test, the strain increases in direct proportion to the increase in stress so that, on the graph, a straight-line relationship is maintained. During this stage, the specimen behaves in an elastic manner such that when the load is removed, all deformation disappears, and the specimen returns to its original dimensions (however, see *elastic after effect*). The slope of the straight-line stage, mathematically the stress divided by the strain, is variously termed the elastic modulus, the tensile modulus or Young's modulus. At some point, the straight-line relationship will cease to hold. This point and the associated stress are referred to as the limit of proportionality.

With many materials, a further small increase in load may introduce further elastic deformation, but the material soon reaches its elastic limit. Increasing the stress above this level then produces a combination of elastic deformation and plastic deformation, predominantly the latter. Plastic or permanent deformation/set is defined as that deformation not recovered by removal of the load and is measured as plastic strain. The position on the stress/strain curve at which plastic deformation commences is also loosely termed the "yield point," but the stricter use of this term refers to the phenomenon in some materials, particularly some steels, whereby at the yield point, an incremental increase in strain occurs without any increase in stress. The stress at the yield point is termed the "yield stress," which gives the yield strength. As further load is applied beyond the elastic limit and yield point, there will be a period during which deformation is uniform over the full gauge length of the specimen but, ultimately, at some maximum load, the specimen will commence to thin locally, termed "necking." This marks the onset of plastic instability following which the cross section of the neck reduces rapidly, the load registered by the test equipment falls rapidly, and the test piece breaks.

Engineering designs are often based on the stress at which plastic deformation will commence. In the case of many steels and some other metals, the yield point is conveniently identifiable as a distinct inflection, or kink, on the stress/strain graph; indeed, in some test circumstances, the line exhibits two inflections, termed the lower and upper yield points. However, for most metals, the elastic limit, that is, the transition from elastic to plastic deformation, is indistinct. It is normal practice to determine, from the stress/strain graph, the stress required to cause a specified small amount of plastic deformation, usually referred to as a percentage strain or offset. This is determined from the graph by identifying on the strain axis the required level of strain and, from it, drawing a line parallel with the straight-line portion of the stress-strain curve. The point at which this parallel line intersects the curve then identifies the required stress. The strain specified is often 0.2%, and the associated stresses are referred to as the 0.2% proof stress or 0.2% offset. Other percentages may be quoted but the differences, in practical terms, between the various levels of proof stress are small. The maximum load carried by the specimen during the test gives, by calculation based on the original cross section of the specimen, the most common measure of the material tensile strength, variously termed the maximum stress, tensile strength or ultimate tensile strength (UTS), etc. After testing, the broken specimen is reassembled for the gauge length to be remeasured. The increase in gauge length is calculated as a percentage of the original gauge length and reported by terms such as % elongation to failure or, simply, % elongation. Finally, the size of the area at the point of failure is measured to calculate the % reduction in area. The elongation and reduction in area are measures of ductility. In commercial activities, UTS, determined as described earlier, is the most commonly specified measure of material strength. However, references occasionally made to terms such as true stress-strain or true maximum stress. These terms recognize that in the conventional tensile test, all calculations are based on the original cross-section area, despite the progressive reduction in cross section following initial yielding. Calculations that take into account this progressive reduction will provide higher values of UTS than those conventionally calculated. These are termed the true values. See *elastic modulus* and *Young's modulus*.

Tensile Strength

In tensile testing, the ratio of maximum load to original cross-sectional area. Also called *ultimate strength*. Compare with *yield strength* and *tensile test*.

Tensile Stress

A stress that causes two parts of an elastic body, on either side of a typical stress plane, to pull apart. In contrast with *compressive stress*.

Tensile Testing

See *tension testing*.

Tension

The force or load that produces elongation.

Tension Set

The condition in which a plastic material shows permanent deformation caused by a stress, after the stress is removed.

Tension Testing

A method of determining the behavior of materials subjected to uni-axial loading, which tends to stretch the material. A longitudinal specimen of known length and diameter is gripped at both ends and stretched at a slow, controlled rate until rupture occurs. Also known as tensile testing.

Tensometer

A small testing machine capable of small scale tensile compression and then testing.

Tenth-Scale Vessel

A filament wound material test vessel based on a 1/10 subscale of the prototype. See also *filament winding*.

Terminal Erosion Rate

The final steady-state erosion rate that is reached (or appears to be approached asymptotically) after the erosion rate has declined from the maximum value. This occurs in some, but not all, cavitation and liquid impingement tests.

Terminal Period

In cavitation and liquid impingement erosion, a stage following the deceleration period, during which the erosion rate has leveled off and remains approximately constant (sometimes with superimposed fluctuations) at a value substantially lower than the maximum rate attained earlier.

Terminal Phase

A solid solution having a restricted range of compositions, one end of the range being a pure component of an alloy system. The same as *primary phase*.

Terminal Solid Solution

In a multicomponent system, any solid phase of limited composition range that includes the composition of one of the components of the system. See also *solid solution*.

Ternary

Containing three components, in particular alloy systems with three elements.

Ternary Alloy

An alloy that contains three principal elements.

Ternary System

The complete series of compositions produced by mixing three components in all proportions.

Terne

An alloy of lead containing 3%–15% Sn, used as a *hot-dip coating* for steel sheet or plate. The term “long terne” is used to describe terne-coated sheet, whereas a short terne is used for terne-coated plate. Terne coatings, which are smooth and dull in appearance (terne means dull or tarnished in French), give the steel better corrosion resistance and enhance its ability to be formed, soldered, or painted.

Terne Metal

An alloy of typically 80% lead, 20% tin, and 0.2% antimony.

Terneplate

Sheet or plate steel coated by hot-dip processes. The coating, intended to enhance corrosion resistance primarily, also improves formability and solderability. Because of the toxicity of red, however, special precautions are required and fabrication operations. Standard coating-thickness designations for sheet products range from LT10 (no minimum) to LT110 (336 g/m²) total weight both sides based on a triple-spot test. Automobile gasoline–fuel tanks have been the major application, although terneplate also has been used for fuel tanks of lawn mowers and outboard marine motors as well as for roofing and building construction, caskets, and other applications.

Terpolymer

A polymeric system that contains three monomeric units.

Terra-Cotta

A general English term applied to fired, and glazed, yellow and red clay wares; in the United States, it refers particularly to the red-and-brown, square and hexagonal tiles made from common brick clay, always containing iron. Some special terra-cottas are nearly white, while for special architectural work, other shades are obtained. The clays are washed, and only very fine sands are mixed with them in order to secure a fine, open texture and smooth surface. Terra-cotta is used for roofing and for tile floors, for hollow building blocks, and in decorative construction work. Good, well-burned terra-cotta is less than 3.8 cm. thick. Terra-cotta is light, having a density of 1922 kg/m³, and withstands fire and frost.

Tertiary Third

See *creep* for *tertiary creep*.

T

Tesselated Stress

The stress that develops within a material because of local variations from point to point in some physical property. Examples include differences in thermal expansion or elastic modulus between neighboring phrases.

Testing Machine (Load-Measuring Type)

A mechanical device for applying a load (force) to a specimen.

Testpiece

A sample of some larger item that has been prepared for some form of testing to determine the properties of the larger item.

Tetra

Four.

Tetrachloroethane

A colorless liquid employed as a solvent for organic compounds such as oils, resins, and tarry substances. It is an excellent solvent for sulfur, phosphorus, iodine, and various other elements. It is used as a paint remover and bleacher, as an insecticide, and in the production of other chlorine compounds. It is also called *acetylene tetrachloride* and is made by the combination of chlorine and acetylene. It is narcotic and toxic, and the breathing of the vapors is injurious. Mixed with dilute alkalis, it forms explosive compounds. In the presence of moisture, it is very corrosive to metals. Mixed with zinc dust and sawdust, it is employed as a smoke screen.

Tetragonal

At least three mutually perpendicular axes, two equal in length and unequal to the third.

Tetrahedron

A solid object with four faces, in particular, a pyramid with three sides and a base.

Tex

A units for expressing linear density equal to the mass of weight in grams of 1000 m of filament, fiber, yarn, or other textile strand.

Textile Fibers

Natural fibers constitute one of man's oldest sources of building materials. There is evidence to indicate that weaving and probably spinning were not unknown to our Stone Age ancestors. It is important to realize that there is no such thing as a natural textile fiber, although today there are human-made textile fibers. There are only natural fibers that have been diverted from their original function by mankind for use in textiles.

In man's search for fibers that can be used to further our own ends, literally dozens of naturally occurring fibers have been investigated. Only 23 are readily recognized by most textile authorities as being of commercial importance, and one fiber alone, cotton, accounts for approximately 70% of the total fibers consumed by the world

population for textile purposes. If, however, this listing of natural fibers is carefully reviewed, it will be found that all fibers can be grouped into six different types of spinnable fibers, each differing fundamentally with respect to molecular and morphological structure. The distinctive characteristics possessed by the fibers of the six groups are such that the groups may be subjectively described as cotton-like, linen-like, sisal-like, wool-like, silk-like, and asbestos-like.

Textile

A textile is a material made mainly of natural or synthetic fibers. Modern textile products may be prepared from a number of combinations of fibers, yarns, plies, sheets, foams, furs, or leather. They are found in apparel, household and commercial furnishings, articles, and industrial products. Materials made directly from plastic sheet or film, leather, fur, or film are not usually considered to be textiles.

The term *fabric* may be defined as a thin, flexible material made of any combination of cloth, fiber, or polymer (film, sheet, or foams); *cloth* as a thin, flexible material made from yarns; *yarn* as a continuous strand of fibers; and *fiber* as a fine, rodlike object in which the length is greater than 100 times the diameter. The bulk of textile products is made from cloth.

The natural progression from raw material to finished product requires the cultivation or manufacture of fibers; the twisting of fibers into yarns (spinning); the interlacing (weaving) or interlooping (knitting) of yarns into cloth; and the finishing of cloth prior to sale.

Spinning Processes

The ease with which a fiber can be spun into yarn is dependent upon its flexibility, strength, surface friction, and length. Exceedingly stiff fibers or weak fibers break during spinning. Fibers that are very smooth and slick or fibers that are very short do not hold together. To varying degrees, the common natural fibers (wood, cotton, and linen) have the proper combinations of the aforementioned properties. The synthetic fibers are textured prior to use to improve their spinning properties by simulating the convolutions of the natural fibers. Natural and synthetic filament fibers, because of their great length, need not be twisted to make useful yarns.

The properties of a yarn are influenced by the kind and quality of fiber, the amount of processing necessary to produce the required fineness, and the degree of twist. The purpose of the yarn determines the amount and kind of processing. The yarn number (yarn count) is an indication of the size of a yarn—the higher the number, the finer the yarn. The degree of twist is measured in turns per inch (tpi) and is varied from three to six times the square root of the yarn number for optimal performance.

The conversion of staple fiber into yarn requires the following steps: picking (sorting, clearing, and blending), carding and combing (separating and aligning), drawing (reblending), drafting (reblended fibers are drawn out into a long strand), and spinning (drafted fibers are further attenuated and twisted into yarn).

Textile Oil

(1) An oil used to lubricate thread or yarn to prevent breakage during spinning and weaving. (2) An oil acceptable for direct contact with fibers during textile production.

Textural Stress

Same as *tesselated stress*.

Texture

In a polycrystalline aggregate, the state of distribution of crystal orientations. In the usual sense, it is synonymous with *preferred orientation*, in which the distribution is not random. Not to be confused with *surface texture*. See also *fiber* (metals) and *fiber texture* (metals).

Texture

(1) The characteristics of a surface such as roughness, alignment, and sharpness of topographical features. (2) Preferred orientation. See *orientation*.

TGA

See *thermogravimetric analysis*.

Thallium

A soft bluish-white metal (symbol Tl) thallium resembles lead but is not as malleable. The specific gravity is 11.85 and melting point 302°C. At about 316°C, it ignites and burns with a green light. Electrical conductivity is low. It tarnishes in air, forming an oxide coating. It is attacked by nitric acid and by sulfuric acid. The metal has a tensile strength of 9 MPa and a Brinnell hardness of 2. Thallium–mercury alloy, with 8.5% thallium, is liquid with a lower freezing point than mercury alone, –60°C, and is used in low-temperature switches. Thallium–lead alloys are corrosion resistant and are used for plates on some chemical-equipment parts.

Applications

The major use for thallium is as a rodenticide and insecticide. The sulfate compound is most commonly a ploy for this application; therefore, the largest commercial sale of the element is in the form of the sulfate. Thallium sulfate is a heavy white crystalline powder, odorless, tasteless, and soluble in water. The advantage of this compound over many other rodenticides is that it is not detected by the rodent.

Other commercially available thallium chemicals are thallos nitrate and thallic oxide. Further uses of thallium compounds are as follows: (1) thallium oxisulfide, employed in a photosensitive cell that has high sensitivity to wavelengths in the infrared range; (2) thallium bromide–iodide crystals, which have a good range of infrared transmission and are used in infrared optical instruments; and (3) alkaline earth phosphors, which are activated by the addition of thallium.

Other minor uses for thallium are in glasses with high indices of refraction, in the production of tungsten lamps as an oxygen getter, and in high-density liquids used for separating precious stones from ores by flotation.

Toxicity

Thallium and thallium compounds are toxic to humans as well as other forms of animal life. Therefore, special care must be taken that thallium is not touched by persons handling it. Rubber gloves should be used in handling both the metal and its compounds. Proper precautions should be taken for adequate ventilation of all working areas.

Theoretical Density

The density of a material calculated from the number of atoms per unit cell and measurement of the lattice parameters.

Theoretical Electrode Force

The force, neglecting friction and inertia, in making spot, seam, or projection welds by resistance welding, available at the electrodes of a resistance welding machine by virtue of the initial force application and the theoretical mechanical advantage of the system.

Theoretical Stress-Concentration Factor

See *stress-concentration factor*.

Theoretical Throat

See *throat of a fillet weld*.

Thermal Activation

The increase in temperature that provides the additional energy input necessary to initiate and maintain a process.

Thermal Aging

Exposure of a material or component to a given thermal condition or a programmed series of conditions for prescribed periods of time.

Thermal Alloying

The act of uniting two different metals to make one common metal by the use of heat.

Thermal Analysis

A method for determining transformations in a metal by noting the temperatures at which thermal arrests occur. These arrests are manifested by changes in slope of the plotted or mechanically traced heating and cooling curves. When such data are secured under nearly equilibrium conditions of heating and cooling, the method is commonly used for determining certain critical temperatures required for the construction of *phase diagrams*.

Thermal Conductivity

(1) Ability of a material to conduct heat across a temperature gradient. All materials conduct heat by the transmission of vibration between neighboring atoms and molecules. Metals also conduct energy via the cloud of free electrons that surround the atoms in the crystal lattice, a much more efficient process, hence the better thermal conductivity of metals. (2) The rate of heat flow, under steady conditions, through unit area, per unit temperature gradient in the direction perpendicular to the area. It is usually expressed in English units as Btu per square feet per degrees Fahrenheit (Btu/ft²/°F). It is given in SI units as watts per meter kelvin (W/m K).

Thermal Cutting

(1) A group of cutting processes that melts the metal (material) to be cut. (2) Cutting by means of thermal processes such as electrical

T

arc and oxyacetylene, which heat and melt the material. The term includes processes in which excess oxygen (including air) is injected to assist cutting by reacting with the material and blasting away molten material and oxide. Powder coating is a variant in which a powder is injected to assist the process largely by a scouring action. See also *air carbon arc cutting*, *arc cutting*, *carbon arc cutting*, *electron beam cutting*, *laser beam cutting*, *metal powder coating*, *oxyfuel gas cutting*, *oxygen arc cutting*, *oxygen cutting*, and *plasma arc cutting*.

Thermal Cycling

The cyclic change in thermal environment.

Thermal Decomposition

(1) The decomposition of a compound into its elemental species at elevated temperatures. (2) A process whereby fine solid particles can be produced from a gaseous compound. See also *carbonyl powder*.

Thermal Electromotive Force

The *electromotive force* generated in a circuit containing two dissimilar metals when one junction is at a temperature different from that of the other. See also *thermocouple*.

Thermal Embrittlement

Intergranular fracture of maraging steels with decreased toughness resulting from improper processing after hot working. Thermal embrittlement occurs upon heating above 1095°C and then slow cooling through the temperature range of 980°C–815°C and has been attributed to precipitation of titanium carbides and titanium carbonitrides at austenite grain boundaries during cooling through the critical temperature range. See also *maraging steels*.

Thermal Endurance

The time required at a selected temperature for a material or system of materials to deteriorate to some predetermined level of electrical, mechanical, or chemical performance under prescribed test conditions.

Thermal Etching

(1) Heating a specimen (usually a ceramic) in air, vacuum, or inert gases in order to delineate the grain structure. Used primarily in high-temperature microscopy. (2) Usually the same as heat tinting but where the terms are differentiated. Thermal etching is carried out in a vacuum, oxidation is prevented, and some diffusion effects are subsequently observable.

Thermal Expansion

The change and waste of a material with change in temperature. See also *coefficient of thermal expansion*.

Thermal Expansion Molding

In forming of plastics, a process in which elastomeric tooling details are constrained within a rigid frame to generate consolidation pressure by thermal expansion during the curing cycle of the autoclave molding process.

Thermal Fatigue

Fracture resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses and a structure.

Damage, particularly cracking, resulting from thermal cycling. This form of damage is differentiated from repeated creep loading, which is seen as the simple loading and unloading of a component at a high temperature. The critical feature of thermal fatigue is that at some position, the normal thermal expansion (less commonly contraction) is constrained by neighboring material that has not expanded to the same extent because of a difference in temperature or, less common, a difference and coefficient of expansion. This induces localized stresses. In the simplest case, the stresses remain within the elastic range and disappear when the temperature gradient flattens. The result was a simple fatigue cycle leading to fatigue cracking; some damage may occur because of the high temperature, but it can be regarded as hot potential damage rather than creep in its usual sense. In more severe cases, the temperature differential is sufficient to induce, locally, stresses that exceed yield at the temperature reached. In many practical cases, the situation is one where a small volume of material, perhaps an edge or corner, rises rapidly to its high operating temperature but its expansion is constrained by the large surrounding volume rising in temperature much more slowly. As a result the high temperature, material yields in compression. When, subsequently, the temperature gradient flattens as the surrounding material leads to the operating temperature, the yielded material, being of reduced dimensions, reverts to a tensile stress. This tensile stress remains active at the operating temperature causing creep. The time spent under load and at temperature during each cycle is termed the dwell period. More severe temperature gradients or combinations of thermal and imposed service loads can cause more complex cycles of stress and plastic deformation. In some cases, material may experience both plastic compression and plastic extension during each thermal cycle; in other cases, the component may progressively extend or compress over a series of cycles, sometimes termed ratcheting or shortening. See *copper shortening*. In addition to the effects of the thermomechanical cycle, thermal fatigue is often accelerated by corrosion and oxidation effects. Such attack may help both crack initiation and propagation by, for example, preferential oxidation at grain boundaries or by forming stress raising, sharp tipped cracks in oxide films. Depending upon the relative contributions of the thermomechanical and the corrosion effects, the attack may become a form of high-temperature corrosion fatigue. See also *craze cracking*.

Thermal Inspection

A nondestructive test method in which heat-sensing devices are used to measure temperature variations in components, structures, systems, or physical processes. Thermal methods can be useful in the detection of subsurface flaws or voids, provided the depth of the flaw is not large compared to its diameter. Thermal inspection becomes less effective in the detection of subsurface flaws as the thickness of an object increases, because the possible depth of the defects increases.

Thermal Instability

The tendency to distort as the temperature is raised. The phenomenon results from various effects and can have various consequences. For example, small variations of thermal expansion coefficient within a component may induce distortion that disappears on cooling. This is difficult to eliminate. In other cases, a component will contain

significant levels of residual stress, so that on heating, it experiences creep relaxation or even yield. The resultant dimensional change does not disappear on cooling, and full stability can usually be achieved by stress relief, sometimes termed a *thermal stability soak* or *cycle* at a temperature in excess of normal operating temperature.

Thermal Noise

The electrical noise produced in a resistor by thermally generated currents. These currents average zero but produce electrical power having a nonzero average, which can affect instrument response. Also known as *Johnson noise*.

Thermal Paint/Crayons/Strips

Materials that show some physical change, usually a color change, as they reach some predetermined temperature. Series of such materials, covering a wide range of temperature, are available for use as a form of temperature measurement.

Thermal Rating

The maximum or minimum temperature at which a material or component will perform its function without undue degradation.

Thermal Resistance

A measure of a body's ability to prevent heat from flowing through it, equal to the difference between the temperatures of opposite faces of the body divided by the rate of heat flow. Also known as heat resistance.

Thermal Severity Number

A means for quantifying the cooling capacity of a joint to be welded. Satisfactory welding of steel is critically dependent on avoiding excessive cooling rates otherwise hardening and cracking will occur, see *steel*. The cooling rate is directly dependent on the cross section of the material conducting the heat away, and the thermal severity number (TSN) is a measure of the total of the available conduction paths and units of $\frac{1}{4}$ in. For example, a butt joint between two pieces of plate $\frac{1}{4}$ in. thick would have a TSN of 2 (two conduction paths each one unit), and a tee joint between 1 in. plates would have a TSN of 12 (three conduction paths each four units). The TSN is correlated with other inputs to indicate any requirements for preheating the joint, see *weldability*. Also see *controlled thermal severity test*.

Thermal Shock

(1) The development of a steep temperature gradient and accompanying high stresses within a material or structure. (2) Effects, particularly high stress and resultant cracking, or less common spalling, resulting from severe temperature gradients with constraint of the associated thermal expansion or contraction. Compared with thermal fatigue, which results from broadly similar factors, the term thermal shock usually implies a small number of thermal cycles and the development of damage immediately when the temperature change is imposed.

Thermal Spray Powder

A metal, carbide, or ceramic powder mixture designed for use with *hardfacing* and *thermal spraying* operations.

Thermal Spraying

A group of coating or welding processes in which finely divided metallic or nonmetallic materials are deposited in a molten or semimolten condition to form a coating. The coating material may be in the form of powder, ceramic rod, wire, or molten materials.

Thermal spray comprises a group of processes in which a heat source converts metallic or nonmetallic materials into a spray of molten or semimolten particles that are deposited onto a substrate. Any material that does not sublime or decompose at temperatures close to its melting point can be applied by thermal spray, as long as it is available in wire or powder form.

Thermal spray coatings offer practical and economical solutions to a variety of industrial problems. They are most commonly applied to resist wear, heat, oxidation, and corrosion, provide electrical conductivity or resistance, and restore worn or undersized dimensions. Although the coating techniques have been around for some time, ongoing improvements are leading to lower application costs and a better understanding of how these coatings work. When properly selected and applied, thermally sprayed coatings can reduce downtime, lower production costs, and improve production yields.

Thermal spray is somewhat related to the welding process. In welding, the added material is actually fused to the base metal, forming a metallurgical bond, whereas a thermally sprayed coating generally adheres to the substrate through a mechanical bond. Nonetheless, some thermal spray processes are capable of achieving mechanical bond strengths that exceed 70 MPa.

The basic thermal spray technologies include plasma spray, wire arc spray, flame spray, detonation gun, and high-velocity oxygen fuel.

Plasma Spray

The plasma spray process requires a plasma gun or torch to generate an arc, which creates the plasma by ionizing a continuous flow of argon gas that is injected into the arc. The arc is struck between a water-cooled copper anode and a tungsten cathode. This type of process is also referred to as nontransferred arc spraying, because the arc is confined to the plasma gun. It is generally operated at energies in the neighborhood of 40–100 kW.

The high heat of plasma causes a large increase in the volume of inert gas introduced, and this produces a high-speed gas jet that accelerates the molten particles and propels them toward the substrate at high velocities. High particle velocities result in dense coatings and high bond strengths.

The plasma transferred arc process is somewhat of a hybrid between plasma spraying and welding. In this process, an arc is struck between the nonconsumable electrode of the plasma torch and the workpiece itself. The feedstock, in the form of wire or powder, is introduced into the resulting external plasma. The material is melted and puddled onto the substrate, producing a metallurgical bond similar to welding, but with a lot less dilution. This process is capable of producing dense and smooth coatings, but it is not capable of applying ceramics.

Wire Arc Spray

The wire arc spray process, like plasma spraying, requires an electrical heat source to melt materials. In this case, the feedstock consists of two conductive metal wires. These two wires act as electrodes that are continuously consumed as the tips are melted by heat from the electrical arc that is struck between them. An atomizing gas shears off the molten droplets and propels them toward the substrate.

T

The atomizing gas is usually compressed air, but it can also be an inert gas such as nitrogen or argon. Compressed air causes oxidation of metal particles, resulting in a large amount of metal oxide in the coating. Because of this, the coating is harder and more difficult to machine than the source material of the coating. This can be a disadvantage because some coatings have to be ground. However, the increased hardness can also enhance wear resistance.

In addition, the temperature of the arc far exceeds the melting point of the sprayed material, resulting in the formation of superheated particles. Consequently, localized metallurgical interactions or diffusion zones develop, which enable achievement of good cohesive and adhesive strengths.

The wire arc process also operates in higher spray rates than the other thermal spray processes. The spray rate, which is dependent on the applied current, makes this process relatively economical.

Flame Spray

In the flame spray process, powder or wire materials are melted through the release of chemical energy triggered by a combustion process. A fuel gas (or liquid) is burned in the presence of oxygen or compressed air. Acetylene fuel gas is most frequently selected, due to its high combustion temperature of 3100°C and low cost. Propane, hydrogen, MAPP, and natural gas are also common choices. The flame melts the feedstock and also accelerates and propels the molten particles. Compressed shop air is also used to assist and boost the particle velocities. However, a compressed inert gas such as argon or nitrogen is preferred if oxidation is a concern.

The setup of a flame spray system is relatively inexpensive and mobile. A basic setup requires only a flame spray torch, a supply of oxygen, and a fuel gas. To increase safety, the seller might have to be augmented with an enclosed spray booth and exhaust.

Because its particle velocities are lower than those of the other thermal spray processes, flame spray coatings are usually of lower quality; they have higher porosity and lower cohesive and adhesive strengths. However, coating quality can be improved by a “spray-and-fuse” process. After the coating is applied by flame spray, the combustion process is repeated to raise the substrate temperature to the point at which the previously applied coating starts to melt. Fusing temperatures exceed 1040°C. The final coating is extremely dense and well bonded by a metallurgical bond. A disadvantage of this technique is the high substrate temperature required and the possibility for deformation of the part.

Detonation Gun

The detonation gun process involves an intermittent series of explosions, which melt and propel the particles onto the substrate. Specifically, a spark plug ignites a mixture of powder and oxygen–acetylene gas in a barrel. After ignition, a detonation wave accelerates and heats the entrained powder particles. After each detonation, the barrel is purged with nitrogen gas, and the process is repeated several times per second.

Coatings produced by the detonation gun process are of excellent quality. The particle velocities are high, so the coatings are dense and exhibit high bond strengths. The drawback is that the process is relatively expensive to operate. It also produces noise levels that can exceed 140 dB and requires special sound- and explosion-proof chambers.

HVOF Spray

The high-velocity oxygen fuel (HVOF) thermal spray process is closely related to the flame spray process, except that combustion

takes place in a small chamber rather than in ambient air. The HVOF combustion process generates a large volume of gas caused by the formation and thermal expansion of such exhaust gases as carbon dioxide and water vapor.

These gases must exit the chamber through a narrow barrel several inches long. Because of the extremely high pressure created in the combustion chamber, the gases exit the barrel at supersonic velocities, thereby accelerating the molten particles. Although the particles do not reach the speed at which the gases are traveling, they do reach very high velocities. Particle velocities of over 750 m/s have been measured. These high particle speeds, and subsequent high kinetic energy, translate into dense coatings with some of the highest bond strengths possible.

Coating Characteristics

The goal of all these thermal spray processes is to provide a functional coating that meets all of the necessary requirements. The quality of a coating depends on the final function of the coating and can be determined by evaluating a number of coating characteristics.

Characteristics that can be evaluated to determine coating quality include

- Microstructure (porosity, unmelts, oxidation level)
- Macrohardness (Rockwell B or C) and microhardness (Vickers or Knoop)
- Bond strength (adhesive and cohesive)
- Corrosion resistance
- Wear resistance
- Thermal shock resistance
- Dielectric strength

Coating Selection

Metal forming, paper and pulp, paper converting, printing (including offset and flexographic), chemical, petrochemical, textile, infrastructure, food processing, automotive, medical, power generation, and aerospace all take advantage of thermally sprayed coatings. For each application, the coating is selected to perform one or more functions. The five most encountered functions are wear resistance, heat and/or oxidation resistance, corrosion resistance, electrical conductivity or resistance, and the restoration of worn or undersized dimensions.

Basically, coatings fall into three categories: metal/alloys, ceramics, and cermets. Almost every metal and alloy available can be sprayed in some form. Frequent choices include copper, tungsten, molybdenum, tin, aluminum, and zinc. Frequently sprayed alloys include steels (carbon and stainless), nickel/chromium, cobalt-base alloys, nickel-base alloys, bronzes, brass, and babbitts. Ceramic materials are usually metal oxide ceramics such as chromium oxide, aluminum oxide, alumina–titania composites, and stabilized zirconias.

Cermets are coatings that combine a ceramic and a metal or alloy. Two examples include tungsten carbide (the ceramic constituent) in a cobalt matrix, and chromium carbide in a nickel–chromium matrix.

Overall, thousands of different products and components are coated with great success. See also *electric arc spraying*, *flame spraying*, *plasma spraying*, and *powder flame spraying*.

In addition, new applications are developed daily. Unfortunately, it is not possible to provide examples of every application and what coating is best for the specific function—see *Adv. Mater. Proc.*, 154(6), p. 32, 1998.

Thermal Spraying Gun

A device for heating, feeding, and directing the flow of a thermal spraying material.

Thermal Stability

See *thermal instability*.

Thermal Straightening

Same as *hot spot straightening*.

Thermal Stress

(1) Stress produced by restraint of thermal expansion or contraction.
(2) Stresses in a material resulting from nonuniform temperature distribution.

Thermal Taper

See *thermal wedge*.

Thermal Wear

Removal of material due to softening, melting, or evaporation during sliding or rolling. Thermal shock and high-temperature erosion may be included in the general description of thermal wear. Wear by diffusion of separate atoms from one body to the other, at high temperatures, is also sometimes denoted as thermal wear.

Thermal Wedge

The increase in pressure due to the expansion of the lubricant, for example, in a parallel thrust bearing. Thermal distortion of the bearing surfaces may also form a wedge shape. This is referred to as *thermal taper*.

Thermally Induced Embrittlement

See *embrittlement*.

Thermal–Mechanical Treatment

See *thermomechanical working*.

Thermic Lance

A coating process in which an oxyacetylene (or other fuel gas) flame is formed at the tip of a steel tube and directed at the item to be cut. The tube is progressively burned away, and the heat from this reaction adds to the normal heat from the oxyacetylene flame producing very high temperatures. In some cases, additional heat may be developed by inserting steel rods into the tube.

Thermionic

Concerned with the emission of electrons by material at high temperature.

Thermionic Cathode Gun

An *electron gun* that derives its electrons from a heated filament, which may also serve as the cathode. Also termed *hot cathode gun*.

Thermionic Emission

The ejection of a stream of electrons from a hot cathode, usually under the influence of an electrostatic field.

Thermistor

A contraction of thermal resistor, a semiconductor, the electrical resistance of which varies considerably and progressively with temperature.

Thermit Crucible

The vessel in which thermit reactions take place.

Thermit Mixture

A mixture of metal oxide and finely divided aluminum with the addition of alloying metals as required.

Thermit Mold

In *thermit welding*, a mold formed around the parts to be welded to receive the molten metal.

Thermit Reaction/Welding

The thermit process utilizes the powerful exothermic, self-propagating reaction resulting from ignition of finely divided aluminum powder mixed with the oxide of a metal such as iron, chromium, molybdenum, or manganese. The reaction oxidizes the aluminum and reduces the ore to its metal, and the heat released is sufficient to melt even high melting point metals. The process can be used to produce such metals but it is better known for its use in thermit welding. In a typical application, joining rail track, the reaction between the aluminum powder and the iron oxide is initiated in the upper chamber of a refractory mold and superheated molten iron flows down into a lower chamber to fill the gap between, and fuse to, the rail faces. See *thermit welding*.

Thermit Welding

A welding process that produces coalescence of metals by heating them with superheated liquid metal from a chemical reaction between a metal oxide and aluminum, with or without the application of pressure. Filler metal, when used, is obtained from the liquid metal. The process is used primarily for welding railroad track.

Thermochemical Machining

Removal of workpiece material—usually only burrs and fins—by exposure to hot fuel gases that are formed by igniting an explosive, combustible mixture of natural gas and oxygen. Also known as the *thermal energy method*.

Thermochemical Treatment

Heat treatment for steels carried out in a medium suitably chosen to produce a change in the chemical composition of the object by exchange with the medium.

T

Thermocompression Bonding

See preferred term *hot pressure welding*.

Thermocouple

Thermocouples are the most common type of temperature sensor used and nearly 16% of all process instrumentation measures, indicates, or controls temperature. Thomas Johann Seebeck is credited with inventing the thermocouple in 1821. His experiment consisted of two dissimilar metal wires joined at the ends to form a loop with each end held at a different temperature.

Seebeck detected the induced current by the displacement of a compass needle that was near one of the wires. Further study revealed that the temperature gradient induced an electric current and when this circuit was broken at the center, an open-circuit voltage was measured, that is, the Seebeck electromotive force. The thermocouple is based on the concept that for small changes in temperature (T_{hot} to T_{cold}), the voltage is proportional to the temperature difference.

Operating environment and temperature are important considerations for picking the correct thermocouple.

When using a thermocouple, it is very important to understand that the measured voltage is developed along the entire length of the thermocouple. Steep temperature gradients should be avoided because any defect in the wire within the gradient will contribute a large error. Steep gradients may also induce recrystallization and grain growth, thus changing the calibration. In this regard, feeding thermocouples through insulation is critically important because deformation of the wires may produce recrystallization during operation.

Thermocouple Materials

A device for measuring temperatures, consisting of lengths of two dissimilar metals or alloys that are electrically joined at one end and connected to a voltage-measuring instrument at the other end. When one junction is hotter than the other, a *thermal electromotive force* is produced that is roughly proportional to the difference in temperature between the hot and cold junctions. Standard thermocouple materials include

Fe, 44Ni-55Cu, 90Ni-9Cr, 94Ni-Al, Mn, Fe, Si, Co, 84Ni-14Cr-1.4Si, 95Ni-4.4Si-0.15Mg, OFHC Cu, 87Pt-13Rh, Pt, 90Pt-10Rh, 70Pt-30Rh, and 94Pt-6Rh. Nonstandard materials include nickel-molybdenum, nickel-cobalt, iridium-rhodium, platinum-molybdenum, gold-palladium, palladium-platinum, and tungsten-rhenium alloys.

Thermodynamics

The study of the interaction between heat and mechanical energy in any process.

Thermoelastic Instability

In sliding contact, sharp variations of local surface temperatures with the passing of asperities leading to stationary or slowly moving hot spots of significant magnitude.

Thermoelectric Cooling

The extraction of heat by the Peltier effect. See *thermoelectric effects*.

Thermoelectric Effect (s)

This term is used as a synonym for the Seebeck effect or as a collective term for all of the following effects. The Seebeck effect is the electromotive force (emf) due to the difference in temperature between the two junctions of dissimilar conductors in a circuit. The Thompson (alternatively the Kelvin) effect is the emf produced by a difference of temperature between two sites of a conductor or, alternatively, the release or absorption of heat associated with an electrical current flowing between two sites on the conductor, which are at different temperatures. The Peltier effect is the release or absorption of heat as an electric current crosses the junction from one conductor to a dissimilar one.

Thermoformed Plastic Sheet

Thermoplastic sheet forming consists of the following three steps; (1) a thermoplastic sheet or film is heated above its softening point; (2) the hot and pliable sheet is shaped along the contours of a mold, the necessary pressure being supplied by mechanical, hydraulic, or pneumatic force or by vacuum; (3) the formed sheet is removed from the mold after being cooled below its softening point.

Sheet Materials

The following five groups of thermoplastic materials account for the major share of the thermoforming business:

1. *Polystyrenes*: High-impact polystyrene sheet, ABS sheet, biaxially oriented polystyrene film, and polystyrene foam
2. *Acrylics*: Cast and extruded acrylic sheet and oriented acrylic film
3. *Vinyls*: Unplasticized rigid PVC, vinyl copolymers, and plasticized PVC sheeting
4. *Polyolefins*: Polyethylene, polypropylene, and their copolymer films
5. *Cellulosics*: Cellulose acetate, cellulose acetate butyrate, and ethyl cellulose sheet

A sixth group of increasing importance is the linear polycondensation products, such as polycarbonates, polycaprolactam (type 6 nylon), polyhexamethylene adipamide, oriented polyethylene terephthalate (polyester), and polyoxymethylene (acetal) films.

General Process Considerations

Thermoplastic sheets softened between 121°C and 232°C. It is important that the sheets be heated rapidly and uniformly to the optimum forming temperature. The fastest heating is brought about with infrared radiant heaters. Some thermoplastics cannot tolerate such intense heat and require convection heating and air-circulating ovens or conduction heating between platens. In a few instances, the sheets are formed "in line," making use of the heat of extrusion.

The following four basic forming methods and more than 20 modifications are known:

Matched Mold Forming

This process, in which the hot sheet is formed between a registering male and female mold section, employs mechanical or hydraulic pressure.

It is used for corrugating flat rigid sheeting either “in line” or in a separate operation. For continuous longitudinal corrugation, the hot sheet is pulled through a matched mold with registering top and bottom teeth. Transverse corrugation is accomplished with matched top and bottom rolls or molds mounted on an endless conveyor belt or chains.

For stationary molding operations, a rubber blanket, backed with a liquid or inflated by air, frequently replaces the male section. Another modification is the *plug and ring* technique in which the ring acts as a stationary clamping device and the moving plug resembles the top portion of the male mold.

Elastic and oriented thermoplastic sheets possess a plastic memory, that is, they tend to draw tight against the force that stretches them. This property occasionally permits forming against a single mold only.

Slip Forming

A loosely clamped sheet is allowed to slip between the clamps and is “wiped” around a male mold. This process has been used to avoid excessive thinning when forming articles with the draws.

Air Blowing

A hot sheet is blown with preheated compressed air into a female mold.

Variations of this process are *free blowing* without a mold into a bubble, *plug-assist blowing* in which a cored plug pushes the hot sheet ahead before blowing, and *trapped sheet forming* in which a clamping ring slides over the mold before applying the compressed air. The last process is employed in automatic roll-fed packaging machines with biaxially oriented films.

Vacuum Forming

This is the most common sheet-forming process with many modifications. *Modifications of vacuum forming:*

- In *straight vacuum forming*, the hot thermoplastic sheet is clamped tight to the top of a female mold or of a vacuum box that contains a male mold. Drawing sheets into a female mold results in excellent replica of fine details on the outer surface of the drawn articles. Straight vacuum forming has proved excellent for shallow draws; however, in articles with small radii or deeper dimensions, the corners and bottom are excessively thinned out. Employing a female mold with multiple cavities is more economical than forming over a number of the male molds, because it permits smaller spacing between cavities (without bridging), which in turn allows more pieces per sheet. Drawing sheets over a male mold produces articles with the thickest section on top. It is used for the production of 3D geographical maps, because it gives a greater accuracy of registration due to restricted shrinkage.
- *Free vacuum forming* into a hemisphere, without a mold, is similar to free air blowing and is employed with acrylic sheets where perfect optical clarity has to be maintained.
- *Vacuum snapback forming* makes use of the plastic memory of the sheet. The hot sheet is drawn by vacuum into an empty vacuum box, while a male mold on a plug is moved from the top into the box. The vacuum is released at the sheet, still hot and elastic, snaps back against the male mold and cools along the contours of the mold. This method is employed with ABS and plasticized vinyl sheets for the production of cases and luggage shells.
- *Drape forming* is a technique that allows deeper drawing. After clamping and heating, the sheet is mechanically stretched over a male mold, then formed by vacuum,

which picks up the detailed contours of the mold. Acrylic and polystyrene sheets slide easily over the mold, whereas polyethylene sheets tend to freeze on contact with the mold, causing differences in thickness.

- To overcome the problem of thinning, *vacuum plug-assist forming* into a female mold has been developed. Its principle is to force a heated and clamped sheet into a female mold using a plug-assist before applying the vacuum. This technique may be considered a reverse of the snapback method.
- *Vacuum air-slip forming* represents a modification of drape forming and is designed to reduce thinning on deep-drawn articles. It consists of prestretching the sheet pneumatically prior to vacuum forming over a male mold. Prestretching is accomplished either with entrapped air by moving the male mold like a piston in the vacuum chamber or by compressed air.
- There are at least three variations of the *reverse-draw technique*. All employ the principle of blowing a bubble of the hot plastic sheet and pushing a plug in reverse direction into the outside of the hot bubble. This accomplishes a folding operation permitting deeper draws than any other common practice.
- The technique of *reverse draw with plug assist* consists of heating the clamped sheet, raising a female mold so that a sealed cavity is formed, while a bubble is blown upward. The preheated plug assist is lowered and pushes the sheet into the cavity. The final shaping is accomplished with vacuum.
- A variation of this method is *reverse draw with air cushion*. The plug assist is furnished with holes through which hot air is blown downward and pushes the hot sheet ahead of the plug assist, minimizing mechanical contact. This technique is used in forming materials with sharp softening ranges have limited hot strength, such as polyethylene and polypropylene.
- *Reverse draw on a plug* uses a male mold on the plug to preserve the finish of the sheet.

Design and Construction of Vacuum Molds

Depth of draw is a prime factor controlling the wall thickness of the formed article. During straight vacuum forming into a female mold, the depth of draw should not exceed one-half of the cavity width. For drape forming over a male mold, the height-to-width ratio should be 1:1 or less. With plug assist, air slip, or one of the reverse-draw techniques, the ratio may exceed the 1:1 ratio.

Proper air evacuation assists material flow in the desired direction and in uniform wall thickness. In general, deep corners require intensified evacuation. The diameter of vacuum holes should be 0.25–0.6 mm for polyethylene sheets, 0.6–1 mm for other thin-gauge materials, and may increase to 1.5 mm for heavier rigid materials. Sharp bends and corners should be avoided, because they result in excessive stress concentration and in reduction of strength. The forming cycle can be accelerated and maintained by the use of mold temperature controls. Molds for permanent use are cast from aluminum or magnesium alloy.

Finishing

After the article has been formed, it must be cooled, removed from the forming machine, and separated from the remainder of the sheet. Trimming of thin-walled articles can be carried out hot or cold, in

T

the forming machine or after removal. Heavy-gauge articles should be trimmed only after cooling. Clicker dies, high dies, and Walker dies are frequently used. Decorating formed articles is generally accomplished by printing the flat sheet before the forming separation. Formed articles may also be spray coated.

Thermoforming

The process of forming a thermoplastic sheet into a 3D shape after heating it to the point at which it is soft and flowable, and then applying differential pressure to make sheet conform to the shape of a mold or die positioned below the frame. When the thermoplastic material has been reinforced, it should be heated to the point that it is soft enough to be formed without cracking or breaking the reinforcing fibers. There are three basic mold types: female (concave), male (convex), and matched (a combination of the two). (1) In basic female forming, or straight vacuum forming, the heated sheet is positioned over the mold cavity and is pulled into the cavity by vacuum. (2) In basic male forming, also called drape forming, the heated plastic is drawn over the mold. As soon as a seal is created, the vacuum is activated, and the plastic is forced directly against the surface of the mold. See *drape forming*. (3) In matched-mold thermoforming, the stamping force of matched male and female molds is used. The male mold pushes the heated sheet into the female cavity. See (thermoforming variations) *air-slip thermoforming*, *plug-assist thermoforming*, *pressure bubble plug-assist thermoforming*, *trapped sheet*, *contact heat*, *pressure thermoforming*, and *vacuum snapback thermoforming*.

Thermogalvanic Corrosion

(1) Corrosion resulting from an *electrochemical cell* caused by a thermal gradient. (2) Electrochemical corrosion mechanisms in which a primary factor is the difference in temperature between the anode and the cathode. The corroded anode is usually the colder.

Thermogravimetric Analysis

The study of the change in mass of a material under various conditions of temperature and pressure.

Thermomechanical Working

A general term covering a variety of metal-forming processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as *thermal-mechanical treatment*.

Thermometal

An alternative term for bimetallic strips.

Thermometer

Any instrument for measuring temperature.

Thermonuclear

Usually a nuclear reaction in which a dominant factor is the impact of particles having a high kinetic energy such as in the hydrogen bomb.

Thermoplastic

Becoming plastic upon heating and returning to a rigid state on cooling. Capable of being repeatedly softened by an increase in temperature and hardened by a decrease in temperature. These polymeric materials that, when heated, undergo a substantially physical rather than chemical change and that in the softened stage can be shaped into articles by molding or extrusion. The transition usually develops at about 80°C–120°C.

One definition of thermoplastic covers the type of decorating glass enamels or overglaze applied through a hot screen. The media is a wax composition that is heated and added to the enamel powder. On cooling, it forms a solid case that is broken into cubes. The cubes are heated and flow onto a resistance-heated metal screen. When applied on ware, the thermoplastic freezes immediately, and other colors can be superimposed without a drying cycle. Thermoplastic permits wraparound decorations and reduces ware handling losses.

Other thermoplastic materials are used in conjunction with the injection molding of technical ceramics such as spark plugs.

Thermoplastic Continuous-Fiber-Reinforced Materials

These materials are tougher and withstand impacts better. They mold readily and can be recycled. They also have unlimited shelf life and admit no hazardous solvents during processing.

Processing

This continuous-fiber-reinforced thermoplastic (CFRTP) process weaves together strands of powder-resin-coated fibers to produce TowFlex fabrics. This is in contrast to other fabrics where raw reinforcement fibers are first woven then coated. Weaving individual coated strands makes the fiber highly drapable. This is because each strand within the fabric moves freely relative to adjacent strengths. In addition, the strands remain flexible because they are not fully wet out prior to molding. Complete wet out of the fabric comes during the compression-molding process.

CFRTP Basics

Fiber-reinforced thermoplastics are widely used in injection molding. The vast majority of these products use short or chopped fibers. These fibers generally measure less than 6.4 mm and will randomly orient themselves during molding. Typical injection molded parts contain only 20%–30% reinforcement fiber. Short, randomly oriented fibers in low percentages do not provide much reinforcement. And it is often difficult to mold such material into complex, large, or thick-walled parts without voids or knit lines.

In comparison, parts molded from new CFRTPs often contain more than 60% reinforcement. Reinforcement fibers run continuously throughout the entire part in specified directions to help optimize strength and stiffness. CFRTPs contain continuous-reinforcement fiber filaments that are powder coated with melt-fusible thermoplastic particles. The uniformly coated filaments are woven into fabrics or braid, formed into semirigid unidirectional tapes or ribbons, or laminated into panels. The resin particles wet out and consolidate quickly when compression molded.

The first step in compression molding CFRTP fabric is to cut and assemble fabric plies. The plies create a preform that approximates the flat pattern shape of the molded part. Automated cutting equipment such as reciprocating knives or ultrasonic gear may be an option for complicated patterns manufactured in high volume. Steel-rule dies, electric rotary shears, or hand shears/scissors might work

best for lower-volume applications. It is often useful to machine a simple preform fixture with a cavity or recess in the shape of the flat pattern. The assembly fixture helps keep the precut fabric plies in proper order, location, and orientation. This includes any partial plies needed to build up additional thickness in specific areas.

Stack plies are tack welded ultrasonically or via a soldering iron before removal from the fixture. This helps keep them in the right orientation during handling and storage. The preforms have unlimited shelf life and can be produced in large quantities independent of the molding process or molds. They also need no additional layup labor before being compression molded into finished parts. The fabric drapes easily and makes for a straightforward molding process that forms and shapes the flat preform. In contrast, thermoset preimpregnated materials generally require cutting and splicing to mold complex shapes.

Molds

Match steel metal molds give the best surface finish and mold life when molding CFRTP parts. Nickel-plated aluminum molds are good for moderate volumes of material processing below 316°C. Steel molds are mandatory for higher-temperature molding of matrix resins such as polyphenylene sulfide or polyetheretherketone. Registration of the upper to lower mold halves takes place through either guide pins or the mold configuration itself.

Generally, molds are designed to fully “bottom out” on the CFRTP material rather than on thickness stops. This helps maintain pressure on the materials throughout the molding process. Thickness stops, however, are used to maintain flatness and help ensure that the mold does not “rock” during the process. They also establish a minimum parts thickness. Stops should typically be 0.25–0.50 mm lower than the desired nominal parts thickness. For relatively thin parts or plates of less than 3.81 mm, quantity of fabric plies loaded into the mold primarily controls thickness. Thicker parts or plates use a specified preform weight along with the number of plies to control parts thickness.

Compression Molding

CFRTP fabrics generally use three variations of the compression-molding process. All employ conventional equipment and do not need rapid closing speeds or excessive press tonnage.

Single-press/heated-cooled platens: The platens in a single press are heated and cooled to reach the right processing conditions.

This approach applies best in situations requiring a variety of different parts and relatively low volumes that do not need a quick molding cycle. The molding process begins with loading of the preform into the lower mold half. Operators next install the upper mold half and load the complete mold into the press. It is then heated with pressures on the order of 68.6–343 kPa. Low pressure during heating helps ensure good heat transfer and initiates the forming of the preform. Full pressure, 0.68–5.44 MPa, comes during final compaction as the mold reaches its required processing temperature. Next, the press platen is cooled to bring the mold and CFRTP part to the removal temperature.

Hot/cold shuttle press: Hot/cold shuttle presses separate the basic segments of the compression-molding process—heating, cooling, and loading/unloading—for better efficiency. Separate heating and cooled platen presses apply pressure to the mold and CFRTP material. Cycle times are short because molds shuttle between preheated hot presses and precooled cooling presses. Cycle times are particularly fast for relatively thin parts at low-mass molds. Molds do not need individual heating and cooling

systems, which helps reduce costs. Molds for deep-draw parts may need to use heated or cooled press platens or bolsters. These approximate the part shape and mount to the hot and cold presses. This approach helps keep heating and cooling sources close to the material to increase processing speed. The hot/cold shuttle-press approach is useful for combinations of different parts in moderate to high volumes. Here, economics do not justify the expense of heating and cooling provisions in each mold. The hard-pressed station is first preheated to 10°C–37.8°C higher than the desired mold temperature. A preform goes in the lower mold half, the upper mold half lowers into place, and the mold shuttles into the preheated press. Low pressure, 68.6–343 kPa, is applied as the mold heats for good heat transfer and to start preform shaping. Full pressure of 0.68–3.4 MPa or more forces final compaction as the mold reaches the processing temperature range. Next, the hot press opens, pressure releases, and the mold shuttles into the cold fresh station. Full pressure again applies as the mold and material cool enough for part removal.

Single-press/heated-cooled molds: Here, integrally heated and cooled molds mount directly onto press platens. Processing cycles for complex-shaped parts can be fast because mold heating and cooling systems can be close to the CFRTP. Individual molds are more expensive, because each mold must contain integral heating and cooling. Press platens must also have sufficient travel to open wide enough for easy preform loading in part removal. Otherwise, molds would need to be removed from the press for part removal. The single-press/heated-cooled mold approach is especially appropriate for large production runs of a specific part or plate. Manufacturers can amortize molds over a large part count, and speedy processing helps drive cost down. It is also appropriate for large or deep molds where the shuttle process is impractical. The integrally heated and cooled mold halves are usually attached to the press platens to minimize handling. The mold temperature cycles between the processing and part-removal temperatures. The CFRTP preform loads into the mold in the press closes with low pressure, 68.6–343 kPa, for good heat transfer and to initiate preform shaping. The heated mold goes under full pressure, 0.68–3.4 MPa or more, for final compaction and forming. The mold and material then cool, and the part is demolded. Cycle times can be under 5 min depending on the mold mass, parts thickness, and part geometry.

Applications

There have been few commercial applications for CFRTP, however. One reason has been that early product forms of these materials were tougher to process and mold. The development of highly drapable, conformable CFRTP fabrics addresses such shortcomings. They are made from thermoplastic such as nylon, polypropylene, polyphenylene sulfide, polyetherimide, and polyetheretherketone with carbon, glass, or aramid reinforcement fibers. They can easily be molded into complex structural shapes and are ideally suited for production quantities of between 1,000 and 50,000 parts annually.

A CFRTP fabric called RF6 is used to make an eight-dihedral-faced kayak paddle. The paddle surface is said not only to grab the water more effectively than conventional blades but also to release surface pressure at eight precise locations along the outside edge of the blade. This produces a blade that has zero flutter while providing more bite per square inch of surface area. The thin blade design

was made possible by the high stiffness and impact resistance of the CFRTTP material.

Thermoplastic Elastomers

Thermoplastic elastomers (TPEs) are a group of polymeric materials having some characteristics of both plastics and elastomers. They are also called elastoplastics. Requiring no vulcanization or curing, they can be processed on standard plastics processing equipment. They are lightweight, resilient materials that perform well over a wide temperature range.

There are a half-dozen different types of elastoplastic.

Types

TPEs have been traditionally categorized into two classes: block copolymers, which include styrenics copolyesters, polyurethanes, and polyamides; and thermoplastic/elastomer blends and alloys, comprised of thermoplastic polyolefins and thermoplastic vulcanizates.

Conventional TPEs are considered two-phase materials composed of a hard thermoplastic phase that is mechanically or chemically mixed with a soft elastomer phase. The resulting material shares the characteristics of both.

Advantages and Drawbacks

TPEs give engineers several advantages over thermoset rubbers, including lower fabrication costs, faster processing times, little or no compounding, recyclable scrap, and processing by conventional thermoplastic equipment. In addition, the processing equipment consumes less energy and maintains tighter tolerances than that of rubber processing.

There are several drawbacks, however. TPEs have relatively low melting temperatures, making them unusable in high-temperature applications. They usually require drying before molding because they are hygroscopic or moisture absorbing. Manufacturers must use TPEs for high-volume applications for it to be economical. And molders accustomed to working with rubber have little experience using TPE materials and equipment.

Properties

As for material properties, TPEs come in durometers, or hardnesses, ranging from 3 Shore A to 70 Shore D, which roughly translates into going from very soft and flexible to semirigid. Although they have relatively low melt temperatures, TPEs resist continuous exposure to temperatures up to 135°C, with spikes up to 149°C. On the other end of the temperature spectrum, they remain flexible at temperatures down to -69°C. The polymers have outstanding dynamic fatigue resistance, good tear strength, and resist acids and alkalies, ultraviolet light, fuels and oils, and ozone, and maintain their grip in wet and dry conditions.

Advancements and Applications

The latest advancements in TPE formulations are resin blends that adhere directly to engineering thermoplastics without any special features and can be applied by insert molding (over molding) and two-shot injection molding. The new formulations let designers mold grips onto a wider range of thermoplastics, particularly high-strength materials such as high-impact polystyrene, glass-filled

nylon, and polycarbonate, which are commonly used in power tools, sporting goods, and electronics.

New materials are also easier to mold in thin-wall sections, which is crucial for consumer electronics where weight is a concern. Consumer-electronics manufacturers can use TPEs for grip strips, for example, because new resins flow easily across long, thin channels in part molds. Engineers prefer to mold “soft-touch” elastomers onto rigid substrates instead of using adhesives and mechanical locks; yet most elastomers do not provide the necessary adhesion, compatibility, and durability.

To answer these needs, a material system was developed consisting of a rigid and a flexible thermoplastic polyurethane formulation. The two materials—Estaloc thermoplastic and Estane elastomer—have similar chemical makeup. This chemical compatibility helps the two materials form a strong bond without adhesives, giving automotive manufacturers, for example, a “one-stop shop” for interior applications such as ignition bezels.

Copolyether-ester thermoplastic elastomer applications include tubing and hose, V belts, couplings, oil-field parts, and jacketing for wire and cable. Their chief characteristic is toughness and impact resistance over a broad temperature range.

Thermoplastic Fluoropolymers

See *fluoroplastics*.

Thermoplastic Injection Molding

A process in which melted plastic is injected into a mold cavity, where it cools and takes the shape of the cavity. Bosses, screw threads, ribs, and other details can be integrated, which allows the molding operation to be accomplished in one step. The finished part usually does not require additional work before assembling. See also *reciprocating-screw injection molding*.

Thermoplastic Olefins

The olefinics, or thermoplastic olefins (TPOs), are produced in durometer hardnesses from 54A to 96A. Specialty flame-retardant and semiconductive grades are also available. The TPOs are used in autos for paintable body filler panels and air deflectors and as sound-deadening materials in diesel-powered vehicles.

The TPOs have room-temperature hardnesses ranging from 60 Shore A to 60 Shore D. These materials, as they are based on polyolefins, have the lowest specific gravities of all thermoplastic elastomers. They are uncured or have low levels of cross-linking. Material cost is midrange among the elastoplastics.

These elastomers remain flexible down to -51°C and are not brittle at -68°C. They are autoclavable and can be used at surface temperatures as high as 135°C in air. The TPOs have good resistance to some acids, most bases, many organic materials, butyl alcohol, ethyl acetate, formaldehyde, and nitrobenzene. They are attacked by chlorinated hydrocarbon solvents. Compounds rated V-Oby Underwriter Laboratories (UL) 94 methods are available.

Thermoplastic Polyesters

A class of thermoplastic polymers in which the repeating units are joined by ester groups. The two important types are *polyethylene terephthalate* (PET), which is widely used as film, fiber, and soda bottles; and *polybutylene terephthalate* (PBT), which is primarily a molding compound.

Known chemically as polybutylene terephthalate (PBT) and polyethylene terephthalate (PET), the thermoplastic polyester-molding compounds are crystalline, high-molecular-weight polymers. They have an excellent balance of properties and processing characteristics and, because they crystallize rapidly and flow readily, mold cycles are short.

In addition to several unreinforced molding resins, the polyesters are available in glass-reinforced grades. Unreinforced and glass-filled grades are available with UL flammability ratings of 94 HB and 5 V.

Properties

Thermoplastic polymers have excellent resistance to a broad range of chemicals at room temperature including aliphatic hydrocarbons, gasoline, carbon tetrachloride, perchloroethylene, oils, fats, alcohols, glycols, esters, ethers, and dilute acids and bases. They are attacked by strong acids and bases.

High creep resistance and low moisture absorption give the polyesters excellent dimensional stability. Equilibrium water absorption, after prolonged immersion at 22.75°C, ranges from 0.25% to 0.50% and, at 66°C, is 0.52% to 0.60%. Black-pigmented grades are recommended for maximum strength retention in outdoor uses.

Thermoplastic Polyimides

Fully imidized, linear polymers with exceptionally good thermomechanical performance characteristics. Aromatic thermoplastic polyimides are generally produced by the polycondensation reaction of aromatic dianhydrides with aromatic diamines or aromatic diisocyanates in a suitable reaction medium.

Thermoplastic Polypropylene

With long-fiber-reinforced materials, thermoplastic composite extrusions reportedly offer properties superior to those of PVC and polypropylene—as well as more costly engineered thermoplastics like polycarbonates. This development is referred to as very high modulus extrusion (VHME).

Parts reinforced by long-fiber materials have been injection molded for 15 years. But VHME thermoplastic is the first commercial application of long-fiber extrusions. The material consists of a long-fiber-based core for strength and impact resistance, sheathed by inner and outer layers of ABS, polypropylene, or weatherable PVC.

To date, the fibers extruded have been limited to glass and carbon, and the glass fibers are about 1.27 cm long. Quite a number of thermoplastics can be used as the matrix in VHME work. They include polyurethane, polypropylene, ABS, and polycarbonate.

The nylons or polyacetals have not initially been done because current equipment is not capable of processing at that high a temperature.

Applications

Recent applications for VHME include a commercial refrigeration system and the subfloor of a refrigerated semitruck trailer. In the commercial refrigeration application, VHME was used to make a corner support to hold glass in a glass assembly. Engineers chose the material because it offered low thermal conductivity and enough strength to retain the glass. In the trailer application, the material replaces the heavy wood that tended to rot. Aside from its resistance

to rot, VHME produced other benefits. It improved the thermal performance of the unit, and it also reduced the weight about 1 lb/lineal foot. Thus, on the semitrailer, it saved about 184 kg.

Thermoplastic Polyurethanes

Linear (segmented) block copolymers. Such a copolymer consists of repeating groups of diisocyanate and short-chain diol, or chain extender, for a rigid block, and repeating groups of diisocyanate and long-chain diol, or polyol, for a flexible block. Thermoplastic polyurethanes (TPUs) are commonly injection molded, blow molded, or extruded. See *polyurethanes*.

TPU is often the choice for critical tasks because it offers a broad range of high-performance properties. Moreover, it is known for reliability and has a long working life even in harsh end uses. TPUs routinely provide low-temperature flexibility, high abrasion and moisture resistance, and a long storage life.

TPU is a thermoplastic elastomer with many of the same physical and mechanical properties of vulcanized rubber, but with the wider range of processing options, common to other thermoplastic polymers. TPUs, like vulcanized rubber, have low hysteresis, high elongation, and good tensile strength. Processors can also tailor their durometer, or hardness, by varying their internal structure without adding special chemicals or plasticizers.

Urethane chemistry is built around four of the most common elements: carbon, hydrogen, nitrogen, and oxygen. And it uses the molecular urethane linkage (NHCO_2) to connect a series of block copolymers with alternating hard and soft segments. The ratio and molecular structure of these segments determine the specific properties of a TPU grade. The hard segments contain an isocyanate structure while the soft segments consist of different polyols. These polyol segments, either polyether or polyester, are used to distinguish different types of TPUs.

Types and Properties

Polyether TPU provides a softer “feel” or drape than polyester and is generally preferred where there is a skin contact. Compared with polyesters, it offers better moisture vapor transmission rates as superior low-temperature properties. It is inherently stable when exposed to high humidity and is naturally more resistant to fungus, mildew, and microbe attack.

However, polyester TPUs have better abrasion resistance with higher tensile and tear strengths for a given durometer. The polyester version also stands up better to fuels and oils, has superior barrier properties, and does not age as fast thanks to better oxidation resistance. However, polyester TPUs will eventually break down in high humidity.

TPUs are further identified by the chemical makeup of their isocyanate, or hard segment components. TPUs are classified into aliphatics (linear or branched chains) or aromatics (containing benzene rings). Aromatic TPUs are strong, general-purpose resins that resist attack by microbes, stand up well to chemicals, and are usually processed. An aesthetic drawback, however, has the tendency of aromatics to discolor, or yellow, when exposed to ultraviolet (UV) light or low-level gamma sterilization. The addition of UV stabilizers or absorbers can reduce this discoloration.

Aliphatic urethanes, on the other hand, are inherently light stable and resists discoloration from UV exposure or gamma sterilization. They are also optically clear, which makes them suitable laminates for encapsulating glass and security glazings.

From an environmental standpoint, use of TPU often makes sense.

T

Urethane burns more cleanly than polyvinyl chloride and other films that compete in the disposable medical-supply market. Using urethane helps avoid the toxic by-products resulting from incinerating disposables fabricated from PVC. In addition, TPU is also readily recycled.

Thermoplastic Styrenes

The styrenics are block copolymers, composed of polystyrene segments in a matrix of polybutadiene or polyisoprene. Lowest in cost of the elastoplastics, they are available in crumb grades and molding grades and are produced in the durometer harnesses from 35A to 95A.

Thermoplastic Urethanes

Thermoplastic urethanes are of three types: polyester urethane, polyether urethane, and caproester urethane. All three are linear polymeric materials, and therefore do not have the heat resistance and compression set of the cross-linked urethanes. They are produced chiefly in three durometer hardness grades—55A, 80A, and 90A. The soft 80A grade is used where high flexibility is required, and the hard grade 70D is used for low-deflection load-bearing applications.

Thermoplastic Vulcanizates

Thermoplastic vulcanizates (TPVs), a type of thermoplastic elastomer, are more challenging to color because they consist of a blend of polypropylene and very fine ethylene propylene diene terpolymer (EPDM) rubber particles. The EPDM particles make it impossible to develop a clear resin. However, recent developments offer whiter and cleaner TPVs that can produce bright colors. This class of thermoplastic elastomers consists of mixtures of two or more polymers that have received a proprietary treatment to give them properties significantly superior to those of simple blends of the same constituents. The two types of commercial elastomeric alloys or melt-processable rubbers (MPRs) and TPVs. MPRs have a single phase; TPVs have two phases.

Properties

Thermoplastic vulcanizates are essentially a fine dispersion of highly vulcanized rubber in a continuous phase of a polyolefin. Critical to the properties of a TPV are the degree of vulcanization of the rubber and the fineness of its dispersion. The cross-linking and fine dispersion of the rubber phase gives a TPV high tensile strength (7.55–26.78 MPa), high elongation (375%–600%), resistance to compression and tension set, oil resistance, and resistance to flex fatigue. TPVs have excellent resistance to attack by polar fluids and fair-to-good resistance to hydrocarbon fluids. Maximum service temperature is 135°C.

Elastomeric alloys are available to the 55A to 50D hardness range, with ultimate tensile strength ranging from 5.44 to 27.2 MPa. Specific gravity of MPRs is 1.2–1.3; the TPV range is 0.9–1.0.

Uses

In 1981, a line of TPVs, called Santoprene, was commercialized based on EPDM rubber and polypropylene designed to compete with thermoset rubbers in the middle performance range. In 1985, a second TPV, Geolast, based on polypropylene and nitrile rubber was introduced. This TPV alloy was assigned to provide greater oil resistance than that of the EPDM-based material. The nitrile-based

TPV provides a thermoplastic replacement for thermoset nitrile and neoprene because oil resistance of the materials is comparable.

The MPR product line, called *Alcryn*, was introduced in 1985. It is a single-phase material, which gives it a stress-strain behavior similar to that of conventional thermoset rubbers. MPRs are plasticized alloys of partially cross-linked ethylene interpolymers and chlorinated polyolefins.

Thermoreactive Deposition/Diffusion Process

A method of coating steels with a hard, wear-resistant layer of carbides, nitrides, or carbonates. In the thermoreactive deposition/diffusion process, the carbon and nitrogen in the steel substrate diffuse into a deposited layer with a carbide-forming or nitride-forming element such as vanadium, niobium, tantalum, chromium, molybdenum, or tungsten. The diffused carbon or nitrogen reacts with the carbide- and nitride-forming elements in the deposited coating so as to form a dense and metallurgically bonded carbide or nitride coating at the substrate surface.

Thermoset

A resin that is cured, set, or hardened, usually by heating, into a permanent shape. The polymerization reaction is an irreversible reaction known as cross-linking. Once set, a thermosetting plastic cannot be remelted, although most soften with the application of heat.

Thermoset Injection Molding

A process in which thermoset material that has been heated to a liquid state is caused to flow into a cavity or several cavities and held at an elevated temperature for a specific time. After cross-linking is completed, the hardened part is removed from the open mold. The mold used is usually of through-hardened tool steel that has been chrome plated and highly polished.

Thermoset Plastics

Thermoset Composites

Thermoset matrix systems dominate the composites industry because of their reactive nature and ease of impregnation. They begin in a monomeric or oligomeric state, characterized by very low viscosity. This allows ready impregnation of fibers, complex shapes, and a means of achieving cross-linked networks in the cured part. The early high-performance thermoset-matrix materials were called advanced composites, differentiating them from the glass/polyester composites that were emerging commercially in the 1950s. The “advanced” term has come to denote, to most engineers, a resin-matrix material reinforced with high-strength, high-modulus fibers of glass, carbon, aramid, or even boron, and usually laid up in layers to form an engineered component. More specifically, the term has come to apply principally to epoxy-resin-matrix materials reinforced with oriented, continuous fibers of carbon or of a combination of carbon and glass fibers, laid up in multilayer fashion to form extremely rigid, strong structures.

Resin Systems

More than 95% of thermoset composite parts are based on polyester and epoxy resins; of the two, polyester systems predominate in

volume by far. Other thermoset resins used in reinforced form are phenolics, silicones, and polyimides.

Polyesters

They can be molded by any process used for thermosetting resins. They can be cured at room temperature and atmospheric pressure, or at temperatures to 177°C and under higher pressure. These resins offer a balance of low cost and ease of handling, along with good mechanical, electrical, and chemical properties, and dimensional stability.

Polyesters can be compounded to be flexible and resilient, or hard and brittle, and to resist chemicals and weather. Halogenated (chlorinated or brominated) compounds are available for increased fire retardance. Low-profile (smoother surface) polyester compounds are made by adding thermoplastic resins to the compound.

Polyesters are also available in ready-to-mold resin/reinforcement forms—bulk-molding compound (BMC) and sheet-molding compound (SMC). BMC is a premixed material containing resin, filler, glass fibers, and various additives. It is supplied in a dough-like, bulk form and as extruded rope.

SMC consists of resin, glass fiber reinforcement, filler, and additives, processed in a continuous sheet form. Three types of SMC compounds are designated by Owens Corning Fiberglass Corp. as random (SMC-R), directional (SMC-D), and continuous fiber (SMC-C). SMC-R, the oldest and most versatile form, incorporates short glass fibers (usually about 25.4 mm long) in a random fashion. Complex parts with bosses and ribs are easily molded from SMC-R because it flows readily in a mold. SMC-C contains continuous glass fibers oriented in one direction, and SMC-D, long fibers (203–305 mm long), also oriented in one direction.

Moldings using SMC-C and SMC-D have significantly higher unidirectional strength but are limited to relatively simple shapes because the long glass fiber cannot stretch to conform to a shape. These two types of SMC are usually, but not always, used in combination with SMC-R. Various combinations are available that contain a total of as much as 65% glass by weight. These materials are used for structural, load-bearing components.

High-glass-content SMCs are also produced by PPG Industries, designated as XMC. These compounds contain up to 80% glass (or glass/carbon mixtures) as continuous fibers in an X pattern.

XMC is a high-glass content sheet molding compound. In one application which was designed by Motor Wheel Corp., and compression molded by Goodyear. A wheel composed of a three-ply hoop of Goodyear's XMC 65% long-glass and chopped fiber-reinforced resin on the periphery, and multiple plies of high-strength steel molding compound, reinforced with 50% random glass fiber, for the club. Forty percent lighter than a steel wheel and 10% to 20% lighter than an aluminum design, the composite wheel has undergone long-term and accelerated laboratory, proving ground, and field evaluations.

A class of resins produced by dissolving unsaturated, generally linear, alkyd resins in a vinyl-type active monomer such as styrene, methyl styrene, or diallyl phthalate. Cure is effected through vinyl polymerization using peroxide catalysts and promoters or heat to accelerate the reaction. One important commercial type is liquid resins that are cross-linked with styrene and used either as impregnants for glass or carbon fiber reinforcements in laminates, filament-wound structures, and other built-up constructions, or as binders for chopped-fiber reinforcements in molding compounds, such as *sheet molding compound (SMC)* and *bulk molding compound (BMC)*. A second important type is liquid or solid resins that are cross-linked with other esters in chopped-fiber and mineral-filled molding

compounds, such as alkyd and diallyl phthalate. See also *unsaturated polyesters*.

Epoxies

These are low-molecular-weight, syrup-like liquids that are cured with hardeners to cross-linked thermoset structures that are hard and tough. Because the hardeners or curing agents become part of the finished structure, they are chosen to provide desired properties in the molded part. (This is in contrast to polyester formulations wherein the function of the catalyst is primarily to initiate cure.) Epoxies can also be formulated for room-temperature curing, but heat-curing produces higher properties.

Epoxies have outstanding adhesive properties and are widely used in laminated structures. The cured resins have better resistance than polyesters to solvents and alkalies, with less resistance to acids. Electrical properties, thermal stability (to 288°C in some formulations), and wear resistance are excellent.

Phenolics

The oldest of the thermoset plastics have excellent insulating properties and resistance to moisture. Chemical resistance is good, except to strong acids and alkalies.

Reinforced phenolics are processed principally by high-pressure methods—compression molding and continuous laminating—because volatiles are condensed during the molding process. Recently developed injection-moldable grades, however, have made the processing of phenolics competitive with thermoplastic molding in some applications.

Silicones

These have outstanding thermal stability, even in the range of 260°C–371°C. Water absorption is low, and dielectric properties are excellent. Chemical resistance (except to strong alkalies) is very good.

Properties

Typical thermoset composites are brittle and have poor impact resistance. An impact may cause little visible surface damage but make the part dramatically weaker.

Thermoset resins need a chemical reaction, usually brought on by heat, to harden, or cure. The chemical reaction is irreversible; once cured, a thermoset material cannot be reprocessed or reformed. And molding cycle time for thermoset materials is largely determined by the curing time.

Thermosetting

(1) Having the property of undergoing a chemical reaction by the action of heat, catalysts, ultraviolet light, and so on, leading to a relatively infusible state. (2) Materials that, when first heated, can be molded and then “cured,” that is, undergo a chemical change to become rigid. Subsequent heating does not cause softening.

Thermospray

A form of metal spraying in which powdered metal or other materials are injected into a high-temperature flame impinging on the surface to be coated.

T

Thermotropic Liquid Crystal

A liquid crystalline polymer that can be processed using thermoforming techniques.

Thickener

A solid material dispersed of a liquid lubricant to produce a grease. Silica, clays, and metallic soaps are widely used as thickeners.

Thick-Film Circuit

A circuit that is fabricated by the deposition of materials having between 5 and 20 μm (0.2 and 0.8 mils) thickness, such as screen-printed cermet pastes on a ceramic substrate, which are fired in a kiln to create permanent conductive patterns. Compare with *thin-film circuit*.

Thick-Film Lubrication

(1) A condition of lubrication in which the film thickness of the lubricant is appreciably greater than that required to cover the surface asperities when subjected to the operating load, so that the effect of the surface asperities is not noticeable. Also known as full-film lubrication. (2) The formation of a substantial film of lubricant between the faces of a plain bearing. This is the usual design intent, see *oil wedge*. See also *thin-film lubrication* and the term *lubrication regimes*.

Thief

A racking device or nonfunctional pattern area used in the electroplating process to provide a more uniform current density on plated parts. Thieves absorb the unevenly distributed current on irregularly shaped parts, thereby ensuring that the parts will receive an electroplated coating of uniform thickness. See also *robber*.

Thin-Film Circuit

A circuit fabricated by the deposition of material several thousand angstroms thick (such as a circuit fabricated by vapor deposition). Compare with *thick-film circuit*.

Thixotropic

A property of certain gels or adhesive systems to thin upon isothermal agitation (shearing) and to thicken upon subsequent test. The characteristic of a material whereby its viscosity is dependent on the shear rate. In practice, the more rapidly the material is stirred, the more fluid it becomes. The process is reversible so that when stirring ceases, the material becomes more viscous as in the case of nondrip paint. See also *rheocasting*.

Thixotropic Processing**Thixoforming**

A method of producing aluminum castings with performance characteristics said to meet or exceed those of steel forgings with 65% less weight, and up to 25% lower cost, has been developed.

During the process, marketed under the name *thixoforming*, aluminum ingots are heated to the precise temperature at which the

material begins to be transformed from the solid to the liquid state. In this form, it can be cast to make strong, lightweight parts that are cheaper and perform better than many forged steel parts.

The critical technology enabling this process is the temperature control system, which is capable of maintaining a uniform temperature throughout the ingot to within $\pm 1^\circ\text{C}$. It is critical to the process that the entire ingot be precisely in the thixotropic state (borderline liquid/solid). If the center is harder than the exterior, the part will have less beneficial metallurgical properties. The process has reportedly had very good success in the automotive industries.

Thixotropic Casting

Ranging from setter tiles and saggars for use in the electronic ceramics industry, to furnace forehearth shapes for the container glass industry, to kiln-car furniture at structural ceramics, precast shapes offer significant benefits.

A new generation of precast shapes has been developed using a thixotropic casting process. This process provides a smoother surface, more precise tolerances, greater strength, improved thermal shock resistance, higher heat tolerances, and more resistance to chemical attack than traditional refractory castable shapes.

Process

Thixotropic casting uses a dispersion agent that allows the ceramic mix to flow when vibrated without requiring high water content. The mix, vibrated into a plaster of paris mold, deairs and consolidates without the use of a cement-bonding agent. The finely crafted plaster of paris mold provides greater dimensional uniformity than common wooden or metal molds and results in a much smoother surface finish.

The crafting process for plastic molds generally involves four separate steps. The first step is to make an exact model of the end product. A master mold, which is a negative of the model, is then made. Then a case mold is made. The case mold is a replica of the original model and is made to protect the original from damage. From the case mold comes the durable working mold, which is a copy of the master mold and a negative of the case mold.

The four-step process is in place to ensure consistency from mold to mold. Depending on the various idea factory processes, each working mold is used to produce roughly 10–50 pieces. The working mold is then replaced with another, again to ensure manufacturing uniformity.

All shapes produced by the thixotropic casting process are high temperature fired between 1412°C and 1524°C . This develops a ceramic bond that enables the products to withstand greater temperatures for a longer period of time.

The fact that these shapes are made without a cement bond—they use a high-fired ceramic bond, instead—accounts for their high heat tolerance. Above 1371°C , cement-bonded refractories begin to soften, the result of glass phase formation. But firing the shapes to up to 1524°C results in a completely formed ceramic bond that will not readily soften in temperatures above 1371°C .

Firing at high temperatures also has the advantage of adding stability to precast shapes. When you first fire a castable shape with a cement bond, a lot of mineralogical changes take place as the product heats up. It can change the overall size and shape of the product, which can lead to an inconsistent product for the customer. By firing the shapes to 1412°C and beyond, there will be no unexpected or unwanted mineralogical changes when first used. The changes that occur in firing are taken into consideration when

the molds are designed. The result is that the product performs as it was designed.

The firing process for precast-fired shapes is a highly controlled operation. All shapes are fired in a 7-day cycle that includes a precise drying process. The periodic kilns that are used to dry and fire the shapes are temperature controlled to within 20°, which is close tolerance for this type of manufacturing. Even the kiln cars are loaded to facilitate a specific airflow pattern that enhances strength and consistency.

Applications

Typical applications for precast kiln furniture shapes include saggers, setter plates, and pusher tiles.

The most common use is with technical ceramic products that have to be fired at higher-temperature areas—above 1301°C.

Other applications include kiln furniture and structural ceramics. The process can handle very small pieces to the very large pieces like kiln furniture, kiln car shapes, posts, and beams—even tracks.

Other applications for precast shapes include glass contact parts in the container glass industry—stirrers, cover blocks, spouts, plungers, and tubes. These glass tank forehearth shapes enable glass manufacturers to maintain consistency in manufacturing their products.

Shapes are also available with a variety of chemical compositions, depending on the requirements of the application. Compositions range from 50% alumina products to shapes with ultrahigh alumina and alumina/zirconia/silica content.

Thixotropy

A property of certain gels or adhesive systems to thin upon isothermal agitation (shearing) and to thicken upon subsequent tests.

Thomas Converter

A Bessemer converter having a basic bottom and lining, usually dolomite, and employing a basic slag. Similar to Bessemer converter.

Thomson Effect (Alternatively the Kelvin Effect)

The emf produced by a difference of temperature between two sites of a conductor and, conversely, the release or absorption of heat associated with an electrical conductor flowing between two sites on the conductor which are at different temperatures. See also *thermoelectric effect*.

Thoria–Thorium Oxide, ThO₂

Small amounts are added to tungsten for lamp filaments to restrain grain growth during long-term high-temperature service.

Thorium

A soft ductile, silvery-white metal (symbol Th) thorium occurs in nature to about the same extent as lead but so widely disseminated in minute quantities difficult to extract that it is considered a rare metal.

It was once valued for use in incandescent gas mantles in the form thorium nitrate, Th(NO₃)₄, but is now used chiefly for nuclear electronic applications.

For many years, thorium oxide has been incorporated in tungsten metal, which is used for electric light filaments; small amounts of the oxide have also been found to be useful in other metals and alloys. The oxide is employed in catalysts for the promotion of certain organic chemical reactions. Thorium oxide has special uses as a high-temperature ceramic material.

Thoria–urania ceramics are used for reactor fuel elements. They are reinforced with columbium or zirconia fibers to increase thermal conductivity and shock resistance. The metal or its oxide is employed in some electronic tubes, photocells, and special welding electrodes. The metal can serve as a getter in vacuum systems and in gas purification, and it is also used as a scavenger in some metals.

Because of its high density, chemical reactivity, mediocre mechanical properties, and relatively high cost, thorium metal has no market value as a structural material. However, many alloys containing thorium metal have been studied in some detail, and thorium does have important applications as an alloying agent in some structural metals. Perhaps, the principal use for thorium metal, beyond its use in the nuclear field, is in magnesium technology. Approximately 3% thorium, added as an alloying ingredient, imparts to magnesium metal high-strength properties and creep resistance at elevated temperatures. The magnesium alloys containing thorium, because of their lightweight and desirable strength properties, are being used in aircraft engines and an air-frame construction.

Thorium can be converted in a nuclear reactor to uranium-233, an atomic fuel. The system of thorium and uranium-233 gives promise of complete utilization of all thorium in the production of atomic power. The energy available from the world supply of thorium has been estimated as greater than the energy available from all of the world's uranium, coal, and oil combined.

Thorium is a radioactive metallic element, and about 1%–2% is added to tungsten to improve electron emission in applications such as tungsten inert gas (gas tungsten arc) welding electrodes and thermionic valve filaments.

Thread

The helical ridge and groove around a threaded fastener. See *fiber* (composites).

Thread Count

The number of yarns (threads) per inch in either the lengthwise (warp) or crosswise (fill or weft) direction of woven fabrics used for reinforcing plastics.

Thread Rolling

The production of threads by rolling the piece between two grooved die plates, one of which is in motion or between rotating grooved circular rolls. The result is less accurate than machining but may introduce favorable residual stresses. Also known as roll threading.

Threaded Fasteners

Devices such as bolts, studs, and screws and the associated internally threaded nuts or holes, which allow components to be clamped together. See *preload*.

T

Threading

Producing external threads on a cylindrical surface.

1. *Die threading*: A process for cutting external threads on cylindrical or tapered surfaces by the use of solid or self-opening dies.
2. *Single-point threading*: Turning threads on a lathe.
3. *Thread grinding*: See definition under *grinding*.
4. *Thread milling*: A method of cutting screw threads with a milling cutter.

Threading and Knurling (Thermal Spraying)

A method of surface roughening in which spiral threads are prepared, followed by upsetting with a knurling tool.

Three High Mill

See *rolling mill*.

Three-Point Bending

(1) The bending of a piece of metal or a structural member in which the object is placed across two supports, and force is applied between and in opposition to them. (2) A bend test in which the test piece is supported at two points and loaded at a point midway between them. The stress peaks at the central loading point unlike four-point bending. See also *V-bend die*.

Three-Quarters Hard

A *temper* of nonferrous alloys and some ferrous alloys characterized by tensile strength and hardness about midway between those of *half hard* and *full hard* tempers.

Threshold Stress

Threshold stress for *stress corrosion cracking*. The critical gross section stress at the onset of stress corrosion cracking under specified conditions.

Throat Depth (Resistance Welding)

The distance from the centerline of the electrodes or platens to the nearest point of interference for flat sheets in a resistance welding machine. In the case of a resistance seam welding machine with a universal head, the throat depth is measured with the machine arranged for transverse welding.

Throat Height (Resistance Welding)

The unobstructed dimension between arms throughout the throat depth in a resistance welding machine.

Throat of a Fillet Weld

A term that includes the theoretical throat, the actual throat, and the effective throat. (1) The theoretical throat is the distance from the beginning of the root of the joint perpendicular to the hypotenuse of the largest right triangle that can be inscribed within the

fillet weld cross section. This dimension is based on the assumption that the root opening is equal to zero. (2) The actual throat is the shortest distance from the root of the weld to its face. (3) The effective throat is the minimum distance minus any reinforcement from the root of the weld to its face. See also *concave fillet weld* and *convex fillet weld*.

Throat of a Groove Weld

See preferred term *size of weld*.

Throat Opening

See preferred term *horn spacing*.

Through Weld

A nonpreferred term sometimes used to indicate a weld of substantial length made by melting through one member of a lap or tee joint and into the other member.

Throughput

Volume of charge passed in a time unit through a production sintering furnace.

Throw

The distance from the centerline of the crankshaft or main shaft to the centerline of the crankpin or eccentric in crank or eccentric presses. Equal to one-half of the stroke. See also *crank press* and the term *eccentric gear*.

Throwing Power

(1) The relationship between the *current density* at a point on a surface and its distance from the *counterelectrode*. The greater the ratio of the surface resistivity shown by the electrode reaction to the volume resistivity of the electrolyte, the better is the throwing power of the process. (2) The ability of a plating solution to produce a uniform metal distribution on an irregularly shaped *cathode*. Compare with *covering power*.

Thrust Bearing

A bearing in which the load acts in the direction of the axis of rotation.

Thulium

A metallic element, one of the rare earth groups, with little commercial application.

Thyristors

Thyristors (semiconductor controlled rectifiers) made from silicon carbide have been fabricated and tested as prototypes of power-switching devices capable of operating at temperatures up to 350°C. The highest-voltage-rated of these thyristors are capable of blocking current at forward or reverse bias as large as 900 V and can sustain forward current as large as 2 A with a forward potential drop of

–3.9 V. the highest-power rated of these thyristors, which are also the highest-power-rated SiC thyristors, can block current at a forward or reverse bias of 700 V and can sustain an “on” current of 6 Å at a forward potential drop of –3.67 V. The highest-current rated of these thyristors can block current at a forward or reverse bias of 400 V and can sustain an “on” current of 10 Å.

These thyristors feature epitaxial *n*- and *p*-doped layers of 4H-SiC in the sequence *npnp* starting on the substrate; the structure stands in contrast to the *pnpn* structure of common silicon thyristors. The fabrication of the high-quality crystalline structures needed in these layers has been made possible by advances in growth of crystals, epitaxial growth of thin films, doping by both in situ and ion-implantation techniques, oxidation, formation of electrical contacts, and other techniques involved in the fabrication of electronic devices. The above *npnp* 4H-SiC thyristors have been found to exceed the speed of the fastest inverter-grade silicon thyristors.

Two other important parameters for a thyristor are (1) the maximum rate of increase of forward applied voltage that can be applied before the thyristor latches on and (2) the time taken to achieve a high forward current density. The 4H-SiC thyristors show no turn-on even when forward bias was ramped up at a rate of 900 V/μs. Measurements and pulsed operation showed that it took between 3 and 5 ns for these devices to start carrying currents at densities of 2800 Å/cm².

Tide Marks

See *beach marks*.

Tie Bar

A bar-shaped connection added to a casting to prevent distortion caused by uneven contraction between two separated members of the casting.

Tie Line

See *lever rule*.

Ties, Tie Rod Bars

Beams carrying significant tensile loads in a construction or assembly.

TIG Welding

Tungsten inert gas welding; see preferred term *gas tungsten-arc welding*.

Tiger Stripes

Continuous bright lines on sheet or strip in the rolling direction.

Tight Fit

A loosely defined fit of slight negative allowance the assembly of which requires a light press or driving force.

Tile

As a structural material, tile is a burned clay product in which the coring exceeds 25% of the gross volume; as a facing material, any thin, usually flat, square product. Structural tile used for load bearing may or may not be glazed; it may be cored horizontally or vertically. Two principal grades are manufactured: one for exposed masonry construction, and the other for unexposed construction. Among the forms of exposure is frost; tile for unexposed construction where temperatures drop below freezing is placed within the vapor barrier or otherwise projected by a facing, in contrast to roof tile.

Structural tile with a ceramic glaze is used for facing. The same clay material that is molded and fired into structural tile is also made into pipe, glazed for sewer lines, or unglazed for drain tile.

As a facing, clay products are formed into thin flat, curved, or embossed pieces, which are then glazed and burned. Commonly used on surfaces that are subject to water splash or that require frequent cleaning, such vitreous glazed wall tile is fireproof. Unglazed tile is laid as bathroom floor. By extension, any material formed into a size comparable to clay tile is called tile. Among the materials formed into tile are asphalt, cork, linoleum, vinyl, and porcelain.

Tile is a ceramic surfacing unit, usually relatively thin in relation to facial area, made from clay or a mixture of clay of other ceramic materials, having either a glazed or unglazed face and fired above red heat in the course of manufacture to a temperature sufficiently high to produce specific physical properties and characteristics.

Tilt

In electron microscopy, the angle of the specimen relative to the axis of the electron beam; at zero tilt, the specimen is perpendicular to the beam axis.

Tilt Boundary

An interface between two grains or the subgrains of the same grain where the angular misalignment is very small that the boundary is little more than a single plane of dislocations. Also consists of an array of edge *dislocations*.

Tilt Casting/Molding

Casting processes in which the mold is initially tilted to allow the molten metal to be poured gently onto a sloping side. As the mold fills, it is progressively rotated to its vertical position. The process is intended to eliminate turbulence which might entrain dross.

Tilt Furnace

A furnace for the infiltration of copper into porous sintered tungsten for heavy-duty contacts. The furnace is tilted to one position for the separate sintering of the tungsten and melting of the copper, and then tilted to the opposite position to let the melt run to and contact or infiltrate, respectively, the tungsten pieces.

Tilt Hammer

A primitive forge in which a centrally pivoted beam carries the hammer at one end and the other end is struck repeatedly by an eccentric on a rotating shaft. The eccentric raises the hammer, which then falls freely to strike the workpiece on the anvil.

T

The drive could be provided by various sources—often water wheel or steam or even animal power.

Tilt Mold

A casting mold, usually a book (permanent) mold, that rotates from a horizontal to a vertical position during pouring, which reduces agitation and thus the formation and entrapment of oxides. See also *permanent mold*.

Tilt Mold Ingot

An ingot made in a *tilt mold*.

Tilting Pad Bearing

A pad bearing in which the pads are free to take up a position at an angle to the opposing surface according to the hydrodynamic pressure distribution over its surface.

Time Delay (of Yield in Some Steels)

The phenomenon whereby rapid application of a load above the yield stress does not induce immediate yield. This is because a period, typically a few milliseconds, is required for dislocations to break away from the lattice features such as interstitial atoms, to which they are pinned.

Time Profile

A plot of the modulus, damping, or both, of a material versus time.

Time Quenching

A term used to describe a quench in which the cooling rate of the part being quenched must be changed abruptly at some time during the cooling cycle. Same as *martempering*.

Time–Temperature Curve

A curve produced by plotting time against temperature.

Time–Temperature–Transformation Diagram

See *isothermal transformation diagram*.

Timing Marks

Sharp lines produced by slightly changing the direction of the applied tension at regular time intervals. Also known as *arrest marks*.

Tin and Alloys

A silvery-white lustrous metal (symbol Sn), with a bluish tinge, tin is soft and malleable and can be rolled into foil as thin as 0.0051 cm. Tin melts at 232°C. Its specific gravity is 7.298, close to that of steel. Its tensile strength is 27 MPa. Its hardness is slightly greater than that of lead, and its electrical conductivity is about one-seventh that of silver. It is resistant to atmospheric corrosion

but is dissolved in mineral acids. The cast metal has a crystalline structure, and the surface shows dendritic crystals when cast in a steel mold.

It alloys readily with nearly all metals.

Tin is a nontoxic, soft, and pliable metal adaptable to cold working such as rolling, extrusion, and spinning. It is highly fluid when molten and has a high boiling point, which facilitates its use as a coating for other metals. It can be electrodeposited readily on all common metals.

Properties

Tin reacts with strong acids and strong bases but is relatively inert to nearly neutral solutions. In indoor and outdoor exposure, it retains its white-silvery color because of its resistance to corrosion. A thin film of stannic oxide is formed in air, which provides surface protection.

Two allotropic forms exist: white tin (β) and gray tin (α). Although the transformation temperature is 13.2°C, the change does not take place unless the metal is of high purity, and only when the exposure temperature is well below 0°C. Commercial grades of tin (99.8%) resist transformation because of the inhibiting effect of the small amounts of bismuth, antimony, lead, and silver present as impurities.

Alloying elements such as copper, antimony, bismuth, cadmium, and silver increase its hardness. Tin tends rather easily to form hard, brittle intermetallic phases, which are often undesirable. It does not form wide solid solution ranges and other metals in general, and there are a few elements that have appreciable solid solubility in tin. Simple eutectic systems, however, occur with bismuth, gallium, lead, thallium, and zinc.

Tin is rarely used alone; rather, it is generally used as a coating for a base metal or as a constituent of an alloy. The range of useful alloys is extensive and extremely important.

Forms

Tin can be obtained in a number of forms; granulated, mossy, fine powder, sheet, foil, and wire. Tin-base alloys are available in many forms; solder can be obtained in 0.46 kg bars, solid and cored wire, powder, sheet, and foil; babbitt-type metal and casting alloys in bars and ingots; bronze in ingot; continuously cast bars at shapes, sheet, and foil.

Applications

Full use is made of the ductility, surface smoothness, corrosion resistance, and hygienic qualities of tin in the form of foil, pipe, wire, and collapsible tubes. Tin foil is devoid of springiness and is ideal for wrapping food products, as liners for bottle caps, and for electrical condensers. Heavy-walled tin pipe and tin-lined copper pipe are used by the food and beverage industries for conveying distilled water, beer, and soft drink syrups. Tin wire is used for electrical fuses and for packing glands in pumps of food machinery. Collapsible tubes, made by impact extrusion from disks of pure tin, are used for pharmaceutical and food products. Additionally, tin is used in brasses, bronzes, and the babbitts, and in soft solders.

The most important use of tin is for tin-coated steel containers (tin cans) used for preserving foods and beverages. Other important uses are solder alloys, bearing metals, bronzes, pewter, and miscellaneous industrial alloys. Tin chemicals, both inorganic and organic, find extensive use in the electroplating, ceramic, plastic, and agricultural industries.

Tinplate manufacture is now largely a continuous electrolytic process with only a small percentage of production in hot-tinning machines. The coating thickness may be less than 0.01 mm. Heavily coated tinned steel sheet is used in making gas meters and automotive parts such as filters and air coolers.

The electrical industry is a large user of tin-coated steel and copper in the form of connectors, capacitor and condenser cans, and tinned copper wire. Many kinds of food-handling machinery, including holding tanks, mixtures, separators, milk cans, pipes, and valves, are made of tinned steel, cast iron, copper, or brass. The tin coating may be applied by dipping in molten tin or by electrodeposition.

The plating industry utilizes tin as anodes for the electrodeposition of pure tin and tin alloy coatings. Plated tin, either as a matt or bright finish, provides easily solderable surfaces for steel, copper, or aluminum. Tin alloy coatings (tin–copper, tin–lead, tin–nickel, tin–zinc, tin–cadmium, tin–cobalt) have advantages over single-metal plates. They are denser and harder, more corrosion resistant, brighter or more easily buffed, and more protective to basis metals. Tin–copper (12% tin) has the appearance of 24-karat gold and, when lacquered, serves as an attractive finish for jewelry, trophies, wire goods, and hardware. Tin–lead electroplates (40%–65% tin) have excellent corrosion resistance and solderability and are well adapted to the plating of printed circuits and electronic parts. Tin–zinc coatings (75% tin) are a good alternative coating for cadmium in particular applications, and they provide galvanic protection to steel in contact with aluminum. Tin–cadmium coatings (25% tin) are especially resistant to salt vapors and have a number of applications in the aircraft industry and as a coating for fasteners. A tin–nickel coating (65% tin) finds use as an etchant resist in the manufacture of printed circuit boards, as well as an ornamental and highly corrosion-resistant finish for watch parts, scientific instruments, and power connectors. The tin–cobalt alloy (80% tin) has an appearance similar to a chromium deposit and is used to plate fasteners, ancillary office equipment, hinges, kitchen utensils, hand tools, and tubular furniture.

Stannic Oxide (SnO_2)

SnO_2 has by far its largest commercial outlet in the ceramic industry, where it is used either as a white pigment (i.e., opacifier) or as a constituent of colored pigments in the glazes applied to, for example, crockery, lavatory ware, and decorative wall tile.

Tin oxide is an important constituent of ceramic stains for enamels, glazes, and bodies. Pink and maroon colors are obtained with tin oxide, chroton oxide, and vanadium compounds. Tin oxide also is an important color stabilizer for some of the tin-bearing pink, gray, yellow, and blue coloring stains for glazes.

This oxide was formally an important opacifier for enamels on cast iron and sheet steel, although it has been replaced by substitute materials such as antimony, zirconium, titanium, and other compounds. The substitution has been largely for economic reasons, as tin oxide is still recognized as the superior opacifier from the standpoint of quality for both glazes and enamels.

In glass, stannic oxide is an important addition to cadmium–selenium and gold colors, especially reds. Stannous oxide, SnO , is a necessary ingredient in the development of copper ruby glass and is also used to produce black glasses. Stannous oxide is a black powder and is also a component of ruby-red and black glasses. Tin oxide, because of its resistance to solution and most glasses, especially those high in lead oxide, is being used for refractories for special applications, such as glass feeders, and conducting electrodes for electrical resistance melting of glass.

Alloys

Soft Solders

Soft solders constitute one of the most widely used and indispensable series of tin-containing alloys. Common solder is an alloy of tin and lead, usually containing 20%–70% tin. It is made easily by melting the two metals together. With 63% tin, a eutectic alloy melting sharply at 169°C is formed. This is much used in the electrical industry. A more general-purpose solder, containing equal parts of tin and lead, has a melting range of 31°C. With less tin, the melting range is increased further, and wiping joints such as plumbers make can be produced. Lead-free solders for special uses include tin containing up to 5% of either silver or antimony for use at temperatures somewhat higher than those for tin–lead solders and tin–zinc base solders often used in soldering aluminum.

Bronzes

Bronzes are among the most ancient of alloys and still form an important group of structural metals. Of the true copper–tin bronzes, up to 10% tin is used in wrought phosphor bronzes and from 5% to 10% tin in the most common cast bronzes. Many bronzes, which are basically copper–zinc alloys, contain 0.75%–1.0% tin for additional corrosion resistance such wrought alloys as admiralty metal and naval brass, and up to 49% tin in cast leaded bronzes. Among special cast, bronzes are bell metal, historically 20%–24% tin for best tonal quality, and speculum, a white bronze containing 33% tin that gained fame for high reflectivity before glass mirrors were invented. Although soft, conformable, and corrosion resistant, the low mechanical strength of bronze must be boosted by bonding to steel, cast iron, or bronze backing materials.

Pewters

Pewter is an easily formed tin-base alloy that originally contained considerable lead. Thus, because colonial pewter darkened and because of potential toxicity effects, its use was discouraged. Modern pewter is lead-free. The most favorable composition, *Britannia metal*, contains about 7% antimony and 2% copper. This has desired hardness and luster retention, yet it can be readily cast, spun, and hammered.

Alloys that contain from 1% to 8% antimony and 0.5% to 3% copper have excellent castability and workability. For spun pewter products, antimony content is usually below 7%, and pewter casting alloys contain 7.5% antimony and 0.5% copper. Because of the excellent drawing and spinning properties of tin, wrought parts are usually made from pewter that is first cast into slabs and then rolled into sheet.

Babbitt/bearing Metal

Babbitt or bearing metal for forming or lining a sleeve bearing is one of the most useful tin alloys. It is tin containing 4%–8% each of copper and antimony to give compressive strength and a structure desired for good bearing properties. An advantage of this alloy is the ease with which castings can be made or bearing shells relined with simple equipment and under emergency conditions. Aluminum–tin alloys are used in bearing applications that require higher loads than can be handled with conventional babbitt alloys.

Type Metals

Type metals are lead-base alloys containing 3%–15% tin and a somewhat larger proportion of antimony. As with most tin-bearing alloys, these are used and remelted repeatedly with little loss of constituents. Tin adds fluidity, reduces brittleness, and gives a structure that reproduces fine detail.

T

Flake and nodular gray iron castings are improved by adding 0.1% tin to give a fully pearlitic matrix with attendant higher hardness, heat stability, and improved strength and machinability.

Tin is commonly an ingredient in costume jewelry, consisting of pewter-like alloys and bearing metal compositions often cast in rubber molds, in die castings hardened with antimony and copper for applications requiring close tolerances, thin walls, and bearing or nontoxic properties, and in low-melting alloys for safety appliances. The most common dental amalgam for filling teeth contains 12% tin.

Die-Cast Tin Base

Historically, these were the first materials to be die cast. Low melting point and extreme fluidity of these alloys produce sound, intricate castings inexpensively and with little wear on molds. Antimony, copper, and lead are the principal additions to tin in die-casting alloys. These alloys are mainly gravity or centrifugally die cast. Cast tin-alloy parts can be held to tolerances of 0.015 mm/mm, with wall thicknesses down to 0.79 mm. Shrinkage is negligible.

Fusible Tin

Melting temperatures for these alloys are usually below the solidus of eutectic-base tin–lead solders (184°C). Primary alloying elements include bismuth, lead, cadmium, and indium. Most of these alloys provide electrical or mechanical links in safety devices. Other applications include low-temperature solders, seals for glass and other heat-sensitive materials, foundry patterns, molds for low-volume production of plastic parts, internal support for tube bending, and localized thermal treatment of parts.

Tin Powders

Produced by atomization techniques, these powders are available in a number of mesh sizes. They are used in the manufacture of powder-metallurgy parts, and tinning and solder pastes, and in the spray metallization of surfaces.

In small amounts, tin is also combined with titanium, zirconium, and other metals to provide special properties. It is used as an alloy in nodular and gray irons to provide greater strength, increased and uniform hardness, and improve machinability. Tin–nickel and tin–zinc coatings are used in the braking systems of automobiles. The tin–nickel alloy is coated on disk-brake pistons because of its good resistance to wear and corrosion. Tin–zinc is used to plate master cylinders in automotive braking systems.

Noncritical parts such as costume jewelry and small decorative items such as figurines can be made by casting pewter and other low-melting tin-base alloys in rubber molds. Tin die-casting alloys are suitable for low-strength precision parts and bearings for household appliances, engines, motors and generators, and gas turbines. These bearings perform well even at start-up and run-down periods of operation, at which times they carry a heavy, unidirectional load without the benefit of a fully formed hydrodynamic film. Other applications for tin-base die castings include parts for food-handling equipment, instruments, gas meters, and speedometers.

Miscellaneous

Tin is allotropic, changing on cooling below about -20°C (-13.2°C is actual equilibrium temperature) from a fairly ductile body-centered tetragonal structure to a low ductility diamond structure. The damaging formation of the low-temperature phase during services referred to as *tin pest*. Tin offers protection only by excluding the environment. Unlike zinc, tin does not offer sacrificial protection so if a tin coating is scratched the exposed steel corrodes.

See *electrochemistry and galvanizing*. Tin is a major constituent in white metals and solders and is a minor alloying element in some brasses and bronzes.

Tin Can

A can made from tin-plated steel.

Tin Cry

The creaking noise produced by tin and its alloys during deformation.

Tin Foil

Very thin sheet of tin or high tin alloy. Incorrect term for aluminum foil, which is much more common for wrapping foodstuffs and similar applications.

Tin Sweat

The formation of tin-rich beads on the surface of cast bronze due to inverse segregation. It may also occur if bronze is heated close to its melting point. See *sweat*.

Tin Tossing

Oxidizing impurities of molten tin by pouring it from one vessel to one another in air, forming a dross that is mechanically separable.

Tinmans Solder

A soft solder of eutectic composition.

Tin–Nickel Plating

An electroplated coating of nickel and tin, usually on a brass substrate, giving a highly reflective, corrosion resistant, and low friction surface.

Tinning

Coating metal with a very thin layer of molten solder or brazing filler metal. Usually prior to making a soldered or brazed joint.

Tin-Pest

A polymorphic modification of tin that causes it to crumble into a powder known as gray tin. It is generally accepted that the maximum rate of transformation occurs at about -40°C , but transformation can occur at as high as about 13°C .

Tinplate

Tinplate is soft-steel plate containing a thin coating of pure tin on both sides. A large proportion of the tinplate use goes into the manufacture of food containers because of its resistance to the action of vegetable acids and its nonpoisonous character. It solders easily and also is easier to work in dies than terneplate, so that it also is preferred over terneplate for making toys and other cheap articles in

spite of a higher cost. Tinplate is made by the hot-dip process using palm oil as a flux or by a continuous electroplating process.

Processing and Uses

Tinplate manufacture in the United States is largely a continuous, high-speed electrolytic process, with less than 1% of production from hot-tinning machines. Electrolytic tinplate can be produced from either alkaline or acid electrolytes. Tinplates have either tin on each steel surface or a differential tin-coating thickness.

Hot-dipped tinplate is used for special corrosive packs, kitchen utensils, hardware items, and automotive parts. For other industrial applications, hot-dip tin coatings are applied to copper wire and sheet, as well as steel and cast iron parts. Examples are tinned copper and copper alloy strip for manufacture of electrical connectors and tinned food-processing equipment. Hot-dip tin-lead (terne) coatings find service as coatings for gasoline tanks, roofing materials, electronic applications, radiator water tubes, and component leads.

Tinsel

A decorative lustrous material usually as thin strands of foil. It was originally an alloy of about 60% zinc and 40% lead but now often some plastic material.

Tint Etching

Immersing metallographic specimens in specially formulated chemical etchants in order to produce a stable film on the specimen surface. When viewed under an optical microscope, these surface films produce colors, which correspond to the various phases in the alloy. Also known as *color etching*.

Tinting

See *heat tinting*.

Tin-Zinc Plating

An electroplated coating of an alloy of tin and zinc, typically about 75% tin and 25% zinc. The coating on steel offers corrosion protection close to that of zinc alone (see *galvanizing*) but is more readily soft soldered.

Tip Skid

See preferred term *electrode skid*.

TIR

Abbreviation for *total indicator reading*.

Titanates

Titanates are compounds made by heating a mixture of an oxide or carbonate of a metal and titanium dioxide. High dielectric constants, high refractive indices, and ferroelectric properties contribute primarily to their commercial importance.

Ferroelectricity may be described as the electric analogue of ferromagnetism. As a field is applied to a ferroelectric material, a

nonlinear relationship between polarization and field (similar to the magnetization curve for iron) is observed. This increase in polarization is a function of the orientation of ferroelectric domains within the crystal.

As these domains become aligned, a saturation point is reached. If the field is now removed, the domains tend to remain aligned, and a finite value of polarization (called remanent polarization) can be measured. Extrapolation of the polarization at high field strength to zero field gives a somewhat higher value (spontaneous polarization).

To eliminate the remanent polarization, the field must be applied in the opposite direction, and the field required to return to the original state is called the coercive field. On further increase in the electric field, polarization in the opposite direction is achieved. This behavior leads to a characteristic ferroelectric hysteresis loop as the field is alternated.

Type of Materials

Titanates, for the most part, are prepared by heating a mixture of the specific oxide or carbonate with titanium dioxide. Titanium dioxide is of exceptionally high refractive index for a white oxide (2.6–2.9 for the rutile form, 2.5 for anatase) and due to its high refractive index finds wide application as a white pigment of high reflectance for the opacification of paint, plastics, rubber, paper, and porcelain enamels.

For electronics, polycrystalline (ceramic) titanium dioxide with its moderately high dielectric constant (–95) has been used as a capacitor; it does not show ferroelectric behavior. Titanium dioxide is normally an insulator, but in the oxygen deficient state when some of the Ti^{4+} sites are occupied by Ti^{3+} ions, it becomes an “*n*-type” semiconductor with conductivities in the range $1\text{--}10/\Omega\text{ cm}$.

Barium Titanate

Barium titanate crystals, BaTiO_3 , are made by die-pressing titanium dioxide and barium carbonate and sintering at high temperatures. This crystal belongs to the class perovskite in which the closely packed lattice of barium and oxygen ions has a barium ion in each corner and an oxygen ion in the center of each face of a cube with the titanium ion in the center of the oxygen octahedron. For piezoelectric use, the crystals are subjected to a high current, and they give a quick response to changes in pressure or electric current. They also store electric charges and are used for capacitors. *Glennite 103* is a piezoelectric ceramic molded from barium titanate modified with temperature stabilizers.

Ceramic barium titanate can be made piezoelectric by applying a polarizing field of about 30 kV/cm at room temperature. The remanent polarization after removal of the polarizing voltage is permanent unless the material is overheated or subjected to high reverse voltages.

The advantages of ceramic barium titanate as a transducer lie in its mechanical strength, chemical durability, and ease of fabrication into virtually any shape desired. Barium titanate transducers, as ultrasonic generators, are used in various applications (emulsification, mixing, cleaning, drilling); other applications include such things as phonograph pickups and accelerometers.

Calcium Titanate

Calcium titanate, CaTiO_3 , occurs in nature as the mineral perovskite. As a ceramic, it has a room-temperature dielectric constant of about 160. It is frequently used as an addition to barium titanate or by itself as a temperature compensating capacitor.

T

Single crystals have been grown by the flame fusion technique; calcium titanate crystals show a strong tendency toward twinning and, although the material is not ferroelectric, the twinning in the crystal shows a marked resemblance to the domain structure observed in barium titanate crystals.

Strontium Titanate

Strontium titanate, SrTiO_3 , has a cubic perovskite structure at room temperature. It has a dielectric constant of about 230 as a ceramic and is commonly used as an additive to barium titanate to decrease the Curie temperature. By itself, it is used as temperature-compensating material because of its negative temperature characteristics. Strontium titanate has been used as a brilliant diamond-like gemstone and is a strontium mesotrititanate. Stones are made up to 4 karat. The refractive index is 2.412. It has a cubic crystal similar to the diamond, but the crystal is opaque in the x-ray spectrum. Single crystals of strontium titanate have been grown by the flame fusion process and strontium titanate is essentially colorless.

Because of its cubic structure, it is somewhat more satisfactory as an optical material than rutile (tetragonal). Strontium titanate crystals show a room-temperature dielectric constant of about 300 with a loss tangent of 0.0003.

Magnesium Titanate

Magnesium titanate, MgTiO_3 , crystallizes as an ilmenite rather than perovskite structure. It is not ferroelectric and is used with titanium dioxide to form temperature-compensating capacitors. It has also been used as an addition agent to barium titanate.

Lead Titanate

PbTiO_3 is used as a less costly substitute for titanium oxide. It is yellowish in color and has only 60% of the hiding power but is very durable and protects steel from rust. Good ceramic specimens of lead titanate are somewhat difficult to prepare owing to the volatility of lead oxide at the firing temperature. Lead titanate is commonly used as a solid solution additive to increase the Curie temperature of barium titanate.

By substitution of zirconium for titanium in lead titanate a solid solution, lead zirconium titanate may be produced. Lead zirconate–lead titanate is a piezoelectric ceramic that can be used at higher temperatures than barium titanate.

Miscellaneous Titanates

The metatitanates of cadmium, manganese, iron, nickel, and cobalt all have an ilmenite rather than perovskite structure. None of these, as far as is known, is ferroelectric, and they are not particularly important electrically other than perhaps as addition agents to barium titanate. Nickel titanate has been grown as a single crystal, and its use as a rectifier has been suggested after the addition of suitable impurities during growth.

Bismuth stannate, a crystalline powder that dehydrates at about 140°C , maybe used with barium titanate in capacitors to increase stability at high temperatures.

Butyl titanate is a yellow viscous liquid used in anticorrosion varnishes and for flame-proofing fabrics. It is a condensation product of the tetrabutyl ester of orthotitanic acid and contains about 36% titanium dioxide.

Titanate fibers can be used as reinforcement in thermoplastic moldings. The fibers, called *Fybex*, can also be used in plated plastics to reduce thermal expansion, warpage, and shrinkage. Titanate fibers in plastics also provide opacity.

Titania

A white water-insoluble powder of composition, TiO_2 , that is produced commercially from the minerals ilmenite and rutile. Used in paints and cosmetics and as an ingredient in porcelain enamels, ceramic whiteware, and ophthalmic glasses. Pure TiO_2 is also used as thin- or thick-film semiconductors. It is also used as white pigment for paints and is a common constituent in the coating of arc welding electrodes.

The best quality of titanium dioxide, or titania, is produced from ilmenite and is higher in price than many white pigments but has great hiding power and durability. Off-color pigments, with a light buff tone, are made by grinding rutile ore. The pigments have fine physical qualities and may be used wherever the color is not important. Titania is also substituted for zinc oxide and lithopone in the manufacture of white rubber goods and for paper filler. The specific gravity is about 4.

Titania crystals are produced in the form of pale-yellow, single-crystal boules for making optical prisms and lenses for applications where the high refractive index is needed. The crystals are also used as semiconductors and for gemstones. They have a higher refractive index than the diamond, and the cut stones are more brilliant but are much softer. The hardness is about 925 Knoop, and the melting point is 1825°C . The refractive index of the rutile form is 2.7 and that of the anatase is 2.5; the synthetic crystals have a refractive index of 2.616 vertically and 2.903 horizontally.

Titanium oxide is a good refractory and electrical insulator. The finely ground material gets good plasticity without binders and is molded to make resistors for electronic use. A microsheet is titanium oxide in sheets as thin as 0.008 cm for use as a substitute for mica for electrical insulation where brittleness is not important. Titania–magnesia ceramics have been made in the form of extruded rods and plates and pressed parts.

Uses

Titanium dioxide is a most important ceramic finish coat for sheet metal products. The opacity of this enamel imparted by titanium dioxide has lowered film thickness of these finishes to the range of organic coatings while retaining the durability of porcelain. These enamels are self-opacified. That is, titanium dioxide is not dispersed as an insoluble suspension during smelting nor is it added to the mill. Rather, titanium dioxide is taken into solution during smelting of the batch and is held in supersaturated solution through fritting. Upon firing the enamel, titanium dioxide crystallizes or precipitates from the glassy matrix.

Trimmers or trimmer condensers employing TiB_2 bodies are used for minute adjustments of capacitance. Normally, the rotor consists of a TiO_2 body. Parts are made with extreme accuracy and are usually supplied in one of three temperature coefficient types. The base is a low-loss ceramic composition.

Mechanical and physical properties of TiO_2 include relatively low strength (MOR 123.5–150.9 MPa; tensile strength 40.8–54.4 MPa, and low thermal conductivity 0.14 cal/cm/s/ $^\circ\text{C}$).

Titanium and Alloys

A metallic element (symbol Ti), titanium occurs in a great variety of minerals. The chief commercial ores of titanium are rutile and ilmenite. In rutile it occurs as an oxide. It is an abundant element but is difficult to reduce from the oxide. High-purity titanium (99.9%) has a melting point of about 1668°C , a density of 4.507 g/cm³, and tensile properties at room temperature of about 234 MPa ultimate

strength, 138 MPa yield strength, and 54% elongation. It is paramagnetic and has low electrical conductivity and thermal expansion.

The commercial metal is produced from sponge titanium, which is made by converting the oxide to titanium tetrachloride followed by reduction with molten magnesium. The metal can also be produced in dendritic crystals of 99.6% purity by electrolytic deposition from titanium carbide. Despite its high melting point, titanium reacts readily in copper and other metals and is much used for alloying and for deoxidizing. It is a more powerful deoxidizer of steel than silicon or manganese.

Melting

Because titanium has a great affinity for oxygen, nitrogen, and hydrogen at elevated temperatures, particularly when molten, all melting operations must be conducted in a vacuum and/or an inert gas atmosphere. The last 10 years has seen a dramatic shift in titanium melting capacity. At least 100 million kg of cold hearth melting capacity has been added to an industry dominated historically by vacuum arc remelting (VAR). Cold hearth melting is a more complex melting process that brings advantages, such as scrap recycling, shape casting (rectangular slabs), and unique alloying capability. Titanium presents special problems during melting because of its high reactivity with oxygen, nitrogen, and carbon. Exposure to these elements during melting causes severe embrittlement, even at low concentrations. This means that all titanium melting must occur in a vacuum or inert atmosphere (argon or helium). It also means that ceramic or graphite containers or liners are not permissible, limiting the design of melting containers to water-cooled copper vessels.

VAR in water-cooled copper crucibles quickly became the standard melting method. When discussing titanium cold hearth melting, one must divide the subject into two major divisions: (1) the production of commercially pure (CP) titanium and (2) the production of titanium alloys. Cold hearth production of CP titanium is done principally using electron beam (EB) melting and occurs at very high melting rates, in some cases greater than 2300 kg/h.

Cold heart melting of CP titanium provides several advantages. First is the use of economical raw materials, such as machined turnings contaminated with tungsten carbide particles. The cold hearth allows with tungsten carbide particles to be removed efficiently by gravity separation. The second advantage, as mentioned earlier, is high production rates. A third advantage is the ability to produce rectangular slabs instead of round ingots.

Although titanium alloys are successfully produced in both plasma and EB cold hearth processes, advantages for cold hearth melting titanium alloys are similarly impressive. As with CP, cold hearth melting of titanium alloys allows the use of many low-cost raw material forms with excellent yield. If EB melting holds an advantage for producing CP, plasma is simpler to use for titanium alloy melting. Because no alloy changes occur during plasma melting, chemistry control is relatively easy. EB melting of alloys containing high vapor pressure components is more problematic. For a common alloy such as Ti-6% Al-4% V, as much as 30% of the aluminum content may evaporate during EB melting. Alloy control in this case requires accurate prediction and compensation for elemental losses, and then very precise process control to meet the predicted losses uniformly throughout the ingot.

A very important technical justification for the use of cold hearth melting for titanium is then the production of premium quality titanium alloys for aircraft turbine engine rotating parts. Inclusion defects contained in the titanium used to produce these parts can be detrimental, leading to low cycle fatigue cracking, engine failure,

and even aircraft loss. In the past 20 years, the aircraft engine producers have increasingly specified the use of cold hearth melting for the most critical titanium parts.

Cold hearth melting provides important mechanisms for the removal of inclusion-forming contaminants from titanium raw materials. High-density inclusion sources, such as tungsten carbide, tungsten, tantalum, and molybdenum, are easily removed by gravity separation (settling) in the cold hearth. By contrast, VAR provides virtually no removal of these defects.

The titanium melting industry has undergone a revolution in melting technology with plasma EB cold hearth melting replacing traditional VAR melting. All major U.S. titanium producers now partly or wholly own large-scale cold hearth melting facilities.

Cold hearth melting provides both economic and technical advantages to the titanium melter. Inexpensive raw materials not usable in other melt methods are readily utilized with excellent yields at high production rates. Potentially damaging inclusion sources may be removed assuring high-quality titanium products for the most demanding and critical applications.

Structure and Properties

Titanium is one of the few allotropic metals (steel is another), that is, it can exist in two different crystallographic forms. At room temperature, it has a close-packed hexagonal structure, designated as the alpha phase. At around 884°C, the alpha phase transforms to a body-centered cubic structure, known as the beta phase, which is stable up to the melting point of titanium of about 1677°C. Alloying elements promote formation of one or the other of the two phases. Aluminum, for example, stabilizes the alpha phase, that is, it raises the alpha to the beta transformation temperature. Other alpha stabilizers are carbon, oxygen, and nitrogen. Beta stabilizers, such as copper, chromium, iron, molybdenum, and vanadium, lower the transformation temperature, therefore allowing the beta phase to remain stable at lower temperatures, and even at room temperature. The mechanical properties of titanium are closely related to these allotropic phases. For example, the beta phase is much stronger, but more brittle than the alpha phase. Titanium alloys therefore can be usefully classified into three groups on the basis of allotropic phases: alpha, beta, and alpha-beta alloys.

Titanium and its alloys have attractive engineering properties. They are about 40% lighter than steel and 60% heavier than aluminum. The combination of moderate weight and high strengths, up to 1378 MPa, gives titanium alloys the highest strength-to-weight ratios of any structural metal. Furthermore, this exceptional strength-to-weight ratio is maintained from -216°C up to 538°C. A second outstanding property of titanium materials is corrosion resistance. The presence of a thin, tough oxide surface film provides excellent resistance to atmospheric and sea environments as well as a wide range of chemicals, including chlorine and organics containing chlorides. As it is near the cathodic end of the galvanic series, titanium performs the function of a noble metal. Titanium and its alloys, however, can react pyrophorically in certain media. Explosive reactions can occur with fuming nitric acid containing less than 2% water or more than 6% nitrogen dioxide and, on impact, with liquid oxygen. Pyrophoric reactions also can occur in anhydrous liquid or gaseous chlorine, liquid bromine, hot gaseous fluorine, and oxygen-enriched atmospheres.

Fabrication

Fabrication is relatively difficult because of the susceptibility of titanium to hydrogen, oxygen, and nitrogen impurities, which cause embrittlement. Therefore, elevated-temperature processing,

T

including welding, must be performed under special conditions that avoid diffusion of gases into the metal. Heat is usually required in postforming operations.

Generally, titanium is welded by gas-tungsten arc, EB, or plasma-arc techniques. Metal inert gas processes can be used under special conditions. Thorough cleaning and shielding are essential because molten titanium reacts with nitrogen, oxygen, and hydrogen and will dissolve large quantities of these gases, which embrittle the metal. In all other respects, gas-tungsten arc welding of titanium is similar to that of stainless steel. Normally, a sound weld appears bright silver with no discoloration on the surface or along the heat-affected zone.

Like stainless steel, titanium sheet and plate work harden significantly during forming. Minimum bend radius rules are nearly the same for both, although spring back is greater for titanium. Commercially pure grades of heavy plate are cold formed or, for more severe shapes, warm formed at temperatures to about 427°C. Alloy grades can be formed at temperatures as high as 760°C in inert gas atmospheres. Tubes can be cold bent to radii three times the tube outside diameter, provided that both inside and outside surfaces of the bend are in tension at the point of bending. In some cases, tighter bends can be made.

Despite their high strength, some alloys of titanium have superplastic characteristics in the range of 816°C–927°C. The alloy used for most superplastically formed parts in the standard Ti-6Al-4V alloy. Several aircraft manufacturers are producing components formed by this method. Some applications involve assembly by diffusion bonding.

Titanium plates or sheets can be sheared, punched, or perforated on standard equipment. Titanium and Ti-Pd alloy plates can be sheared subject to equipment limitations similar to those for stainless steel. The harder alloys are more difficult to shear, so fitness limitations are generally about two-thirds those for stainless steel.

Titanium and its alloys can be machined and abrasive ground; however, sharp tools and continuous feed are required to prevent work hardening. Tapping is difficult because of the metal galls. Coarse threads should be used where possible.

Forms

Commercially pure titanium and many of the titanium alloys are now available in most common wrought mill forms, such as plate, sheet, tubing, wire, extrusions, and forgings. Castings can also be produced in titanium and some of the alloys; investment casting and graphite-mold (rammed graphite) casting are the principal methods. Because of the highly reactive nature of titanium in the presence of such gases as oxygen, the casting must be done in a vacuum furnace. Because of their high strength-to-weight ratio primarily, titanium and titanium alloys are widely used for aircraft structures requiring greater heat resistance than aluminum alloys. Because of their exceptional corrosion resistance, however, they (unalloyed titanium primarily) are also used for chemical-processing, desalination, and power-generation equipment, marine hardware, valve and pump parts, and prosthetic devices.

Unalloyed and Alloy Types

There are five grades of commercially pure titanium, also called unalloyed titanium; ASTM Grade 1, Grade 2, Grade 3, Grade 4, and Grade 7. They are distinguished by their impurity content, that is, the maximum amount of carbon, nitrogen, hydrogen, iron,

and oxygen permitted. Regardless of grade, carbon and hydrogen contents are 0.10% and 0.015% maximum, respectively. Maximum nitrogen is 0.03%, except for 0.05% in Grades 3 and 4. Iron content ranges from as much as 0.20% in Grade 1, the most pure (99.5%) grade, to as much as 0.05% in Grade 4, the least pure (98.9%). Maximum oxygen ranges from 0.18% in Grade 1 to 20.40% in Grade 4. Grade 7, 99.1% pure based on maximum impurity content, is actually a series of alloys containing 0.12%–0.25% palladium for improved corrosion resistance in hydrochloric, phosphoric, and sulfuric acid solutions. Palladium content has little effect on tensile properties, but impurity content, especially oxygen and iron, has an appreciable effect. Minimum tensile yield strength range from 172 MPa for Grade 1 to 483 MPa for Grade 4.

There are three principal types of titanium alloys: alpha or near-alpha alloys, alpha-beta alloys, and beta alloys. All are available in wrought form and some of each type for castings as well. In recent years, some also have become available in powder compositions for processing by hot isostatic pressing and other powder-metallurgy techniques. Titanium alpha alloys typically contain aluminum and usually tin. Other alloying elements may include zirconium, molybdenum, and, less commonly, nitrogen, vanadium, columbium, tantalum, or silicon. Although they are generally not capable of being strengthened by heat treatment (some will respond slightly), they are more creep resistant at elevated temperature than the other two types, are also preferred for cryogenic applications, and are more weldable but less forgeable. Ti-5%Al-2%Sn, which is available in regular and ELI grades (extra-low inertial) in wrought and cast forms, is the most widely used. In wrought and cast form, minimum tensile yield strengths range from 621 to 793 MPa, and tensile modulus is on the order of 107,000–110,000 MPa. It has useful strength to about 482°C and is used for aircraft parts and chemical-processing equipment. The ELI grade is noted for its superior toughness and is preferred for containment of liquid gases at cryogenic temperatures. Other alpha or near-alpha alloys and their performance benefits include Ti-8% Al-1% Mo-1% V (high creep strength to 482 °C), Ti-6% Al-2% Sn-4% Zr-2% Mo (creep resistance and stress stability to 593°C), Ti-6% Al-2% Cb-1% Ta-0.8% Mo (toughness, strength weldability), and Ti-2.25% Al-11% Sn-5% Zr-1% Mo (high tensile strength 931 MPa yield, superior resistance to stress corrosion, and hot salt media at 482°C). Another alpha alloy, Ti-0.3% Mo-0.8% Ni, also known as TiCode 12, is noted for its greater strength than commercially pure grades and equivalent or superior corrosion resistance, especially to crevice corrosion in hot salt solutions.

Titanium alpha-beta alloys, which can be strengthened by solution heat treatment and aging, afford the opportunity of parts fabrication and the more ductile annealed condition and then can be heat treated for maximum strength. Ti-6% Al-4% V, which is available in regular and ELI grades, is the principal alloy, its production alone having accounted for about half of all titanium and titanium alloy production. In the annealed condition, tensile yield strength is about 896 MPa and 13% elongation. Solution treating and aging increase yield strength to about 1034 MPa. Yield strength decreases steadily with increasing temperature, to about 483 MPa at about 510°C for the aged alloy. At 454°C, aged bar has a 1000 h stress-rupture strength of about 345 MPa. Uses range from aircraft and aircraft-turbine parts to chemical-processing equipment, and marine hardware. The alloy is also the principal alloy used for superplastically formed, and superplastically formed and simultaneously diffusion-bonded parts. At 899°C–927°C and low strain rates, the alloy exhibits tensile elongations of 600%–1000%, a temperature range also amenable to diffusion bonding the alloy.

Following are other alpha-beta alloys and their noteworthy characteristics:

- Ti-6% Al-6% V-2% Sn; high strength to about 315°C, but low toughness and fatigue resistance
- Ti-8% Mn; limited use for flat mill products; not weldable
- Ti-7% Al-4% Mo; a forging alloy mainly, but limited use; 1034 MPa yield strength in the aged condition
- Ti-6% Al-2% Sn-4% Zr-6% Mo; high strength, 1172 MPa yield strength, decreasing to about 759 MPa at 427°C; for structural applications at 400°C–540°C
- Ti-5% Al-2% Sn-2% Zr-4% Mo-4% Cr and Ti-6% Al-2% Sn-2% Zr-2% Mo-2% Cr; superior hardenability for thick-section forgings; high modulus—about 117,000–124,000 MPa, respectively; tensile yield strength of about 1138 MPa
- Ti-10% V-2% Fe-3% Al; best of the alloys in toughness at a yield strength of 896 MPa; can also be aged to a yield strength of about 1186 MPa; intended for use at temperatures to about 315°C
- Ti-3% Al-2.5% V; a tubing and fastener alloy primarily, moderate strength and ductility, weldable.

Beta titanium alloys, fewest in number, are noted for their hardenability, good cold conformability in the solution-treated condition, and high-strength after aging. On the other hand, they are heavier than titanium and the other alloy types, their density ranging from about 4.84 g/cm³ for Ti-13% V-11% Cr-3% Al, Ti-8% Mo-8% V-2% Fe-3% Al, and Ti-3% Al-8% V-6% Cr-4% Zr-4% Mo to 5.07 g/cm³ for Ti-11.5% Mo-6% Zr-4.5% Sn, which is also known as Beta III. They are also the least creep resistant of the alloys. Ti-13% V-11% Cr-3% Al, a weldable alloy, can be aged to tensile yield strengths as high as 1345 MPa and retains considerable strength at temperatures to 315°C but has limited stability at prolonged exposure to higher temperatures.

Applications

One of the chief uses of the metal has been in the form of titanium oxide as a white pigment. It is also valued as titanium carbide for hard facings and for cutting tools. Small percentages of titanium are added to steels and alloys to increase hardness and strength by the formation of carbides or oxides or, when nickel is present, by the formation of nickel titanide.

The major portion of the commercial applications of titanium has been in the chemical-processing industries in the form of reactors, vessels, and heat exchangers. The pulp and paper industry has used it in bleaching equipment primarily as chlorine dioxide mixers, while the electrochemical industry has utilized heating and cooling (tubing) coils and anodizing and plating racks. Pumps, valves, thermowells, and other miscellaneous items are additional examples of commercial applications of titanium.

Titanium Carbide

A hard crystalline powder of the composition TiC; titanium carbide is made by reacting titanium dioxide and carbon black at temperatures above 1800°C. It is compacted with cobalt or nickel for use in cutting tools and heat-resistant parts. It is lighter in weight and less costly than tungsten carbide, but in cutting tools, it is more brittle. When combined with tungsten carbide in sintered carbide tool materials, however, it reduces the tendency of cratering in the tool.

Properties

TiC theoretically contains 20.05% carbon and is light metallic gray in color. It is chemically stable and is almost inert to hydrochloric and sulfuric acids. In oxidizing chemicals, such as aqua regia and nitric or hydrofluoric acids, TiC is readily soluble. It also dissolves in alkaline oxidizing melts. When heated in atmospheres containing nitrogen, nitride formation occurs above –1500°C. TiC is attacked by chlorine gas and is readily oxidized in air at elevated temperatures.

The density of TiC is 4.94 g/cm³, Mohs hardness is 9+, microhardness is 3200 kg/mm², and modulus of elasticity is 309,706 MPa. The modulus of rupture at room temperature has been reported as 499.8–843.2 MPa for materials sintered at 2600°C–3000°C. Hot modulus of rupture values are given as 107.78–116.96 MPa at 982°C and 54.4–63.92 MPa at 2200°C.

The melting point of TiC is 3160°C, and electrical resistivity at room temperature is 180–250 μ cm. It can be used as a conductor at high temperatures. Coefficient of thermal expansion between room temperature and 593°C is 4.12 × 10^{−6}/°F. Thermal conductivity is 0.041 cal/cm/s/°C.

Grades and Uses

A general-purpose cutting tool of this type contains about 82% tungsten carbide, 8% titanium carbide, and 10% cobalt binder. Kentanium is titanium carbide and various grades with up to 40% of either cobalt or nickel as the binder, used for high-temperature, erosion-resistant parts. For highest oxidation resistance only, about 5% cobalt binder is used. Other grades with 20% cobalt are used for parts where higher strength and shock resistance are needed and where temperatures are below about 982°C. Oxidation resistance only about 5% cobalt binder is used. Other grades with 20% cobalt are used for parts where higher strength and shock resistance are needed and where temperatures are below about 982°C. This material has a tensile strength of 310 MPa, compressive strength of 3789 MPa, and Rockwell hardness A90. Another for resistance to molten glass or aluminum has a binder of 20% nickel. A titanium carbide alloy for tool bits has 80% titanium carbide dispersed in a binder of 10% nickel and 10% molybdenum. The material has a hardness of Rockwell A93 and a dense, fine-grained structure. Ferro-Tic has the titanium carbide bonded with stainless steel. It has a hardness of Rockwell C55. Machinable carbide is titanium carbide in a matrix of Ferro-Tic C tool steel. Titanium carbide tubing is produced in round or rectangular form 0.25–7.6 cm in diameter. It is made by vapor deposition of the carbide without a binder. The tubing has a hardness above 2000 Knoop and a melting point of 3249°C.

Grown single crystals of titanium carbide have the composition TiC_{0.94}, with 19% carbon. The melting point is 3250°C, density 4.93, and Vickers hardness 3230.

The material is finding new uses in cermet components such as jet engine blades and cemented carbide tool bits. Titanium carbide has a relatively low electrical resistivity (1 × 10^{−4}) and can be used as a conductor of electricity, especially at high temperatures.

Extreme hardness of titanium carbide makes it suitable for wear-resistant parts such as bearings, nozzles, and coating tools. It also serves for special refractories under either neutral or reducing conditions. See also cemented *carbides*, *cermets*, and the term *composite coating*.

Titanium Diboride

The material has a melting point of 2980°C, is stable in HCl and HF acid, but decomposes readily in alkali hydroxides, carbonates, and bisulfates. It reacts with hot sulfuric acid.

T

Processing

Sintered parts of titanium diboride, TiB_2 , are usually produced by either hot pressing, pressureless sintering, or hot isostatic pressing. Hot pressing of titanium diboride parts is conducted at temperatures $>1800^\circ\text{C}$ in vacuum or 1900°C in an inert atmosphere. Hot-pressed parts generally have a final density of $>99\%$ of theoretical. Typical sintering aids used for hot-pressed parts include iron, nickel, cobalt, carbon, tungsten, and tungsten carbide.

Pressureless sintering of TiB_2 is a less expensive method for producing net shape parts. Because of the high melting point of titanium diboride, sintering temperatures in excess of 2000°C often are necessary to promote sintering. Several different sintering aids have been developed to produce dense pressureless sintered parts by liquid-phase sintering. A combination of carbon and chromium, iron, or chromium carbide can be used as a sintering aid to produce pressureless sintered parts with a final density $>95\%$ of the theoretical density. Boron carbide also is added to inhibit grain growth during sintering. These sintering aids as well as atmospheric conditions can be used to lower the sintering temperature necessary for full densification.

Properties

Typical mechanical properties for hot-pressed titanium diboride include a flexural strength of 350–575 MPa, a hardness of 1800–2700 kgf/mm^2 , and a fracture toughness of 5–7 $\text{MPa m}^{-1/2}$. The mechanical property values are dependent on the type of fabrication method used (pressureless sintering vs. hot pressing), the purity of the synthesized powder, and the amount of porosity remaining in the finished part.

The elastic modulus of titanium diboride can range from 510 to 575 GPa and the Poisson ratio is 0.18–0.20. Titanium diboride has a room-temperature electrical resistivity of $15 \times 10^{-6} \Omega \text{ cm}$ and a thermal conductivity of 25 Ω/mK .

Uses

Titanium diboride is used for a variety of structural applications including lightweight ceramic armor, nozzles, seals, wear parts, and cutting tool composites. Titanium diboride also has shown exceptional resistance to attack by molten metals, including molten aluminum, which makes it a useful material for such applications as metalizing boats, molten metal crucibles, and Hall–Heroult cell cathodes because of its intrinsic electrical conductivity. TiB_2 can be combined with a variety of other nonoxide ceramic materials, such as silicon carbide and titanium carbide, and oxide materials, such as alumina, to increase the main strength and fracture toughness of the matrix material.

Titanium Nitride

A hard, high-melting-point ceramic (2950°C) of the composition TiN that is used in cermets and as a coating material for cemented carbide cutting tools. See also *cermets* and the term *carbide tools*.

Titanium nitride whiskers (TiN_w) are single-crystal, acicular-shaped particles of titanium nitride that typically range in size from 0.3 to 1.0 μm in diameter with aspect ratios ranging from 5:1 to 50:1. TiN_w have been produced using several different approaches including carbothermic reduction, laser synthesis, plasma synthesis, solid/solid and solid/gas combustion synthesis, and vapor phase reactions. TiN_w are reported to form from both vapor–solid and vapor–liquid–solid mechanisms.

TiN_w purity can vary from near stoichiometric (nitrogen of 22.7 wt%) to solid solutions of TiCN and TiON where carbon or oxygen substitutes for nitrogen. TiN_w typically form with smooth surfaces and are relatively free from internal defects, which limit the strength of other whiskers such as SiC_w . Unlike SiC_w , TiN_w are electrically conductive and have a coefficient of thermal expansion that is closer to steel and intermetallic materials. TiN_w also have been found to have increased ability with iron-containing metals, alloys, and intermetallic compounds.

Potential applications include reinforcements in various materials including alumina and tungsten carbide–base cutting tool inserts for machining ferrous alloys, iron, nickel, and titanium aluminides (intermetallics), iron, nickel, and titanium metal/alloys and polymers.

Improved chemical resistance of TiN_w with iron compounds makes it an excellent candidate for use as tool inserts for the machining of cast iron and tool steels. The reactivity of SiC_w with iron compounds has limited alumina/ SiC_w cutting tool insert use primarily to superalloys. Alumina/ TiN_w composites have been shown to be machine readable using electric discharge machining.

Other areas of interest include stable reinforcements for iron-, nickel-, and titanium-based intermetallic compounds and metal/alloys and electrically conducting reinforcements for polymers to promote electrical conduction and charge dissipation. TiN_w provide chemical stability and current carrying characteristics desirable in many applications.

Titanium Ores

The most common titanium ores are ilmenite and rutile. Ilmenite is an iron-black mineral having a specific gravity of about 4.5 and containing about 52% titanic oxide, or titania. The ore of India is sold on the basis of titanium oxide content, and the high-grade ore averages about 60% titanium oxide, 22.5% iron, and 0.4% silica. Titanium ores are widely distributed and plentiful. Ilmenite is found in northern New York, Florida, North Carolina, and in Arkansas, but the most extensive, accessible resources are found in Canada. The Quebec ilmenite contains 30% iron. The concentrated ore has about 36% titanium oxide and 41% iron and is smelted to produce pig iron and a slag containing 70% titania, which is used to produce titanium oxide. The beach sands of Senegal are mixed ores, the ilmenite containing 55%–58% titanium oxide and the *zirconiferous quartz* containing 70%–90% zirconia. The beach sands of Brazil are washed to yield a product averaging 71.6% ilmenite, 13% zircon, and 6% monazite.

Rutile is a titanium dioxide, containing theoretically 60% titanium. Its usual occurrence is crystalline or compact massive, with a specific gravity of 4.18 and 4.25 and Mohs hardness 6–6.5. The color is red to brown, occasionally black. Rutile was found in granite, gneiss, limestone, or dolomite. It is obtained from beach sand of northern Florida and Espirito Santo, Brazil, and is also produced in Virginia, in Australia, and in India. Rutile is also produced in Arkansas and Massachusetts. Rutile is marketed in the form of concentrates on the basis of 79%–98.5% titanium oxide. It is used as an opacifier in ceramic glazes and to produce tan-colored glass. It is also employed for welding-rod coatings. On welding rods, it aids stabilization of the arc and freezes the metal of slag.

Titration

A method of determining the composition of a sample by adding known volumes of a solution of known concentration until a given

reaction (color change, precipitation, or conductivity change) is produced. See also *volumetric analysis*.

TIV

Abbreviation for *total indicator variation*.

T-Joint

See *tee joint*.

TLC

See *thin-layer chromatography*.

Toe Crack

A crack in the base metal occurring at the toe of a weld. See *weld crack*.

Toe of Weld

(1) Usually, this term refers to the line on an exposed surface where the boundary of the deposited weld metal meets parent metal. (2) Alternatively, it can refer to any line where the surface boundary of a weld run meets parent metal or a previous weld run. It will be seen that (2) includes positions where the toe has been over run and used by a subsequent deposit. In most cases, references to “toes” without any further description will imply definition (1) but sometimes the terms primary toes and secondary toes are used to refer, respectively, to definitions (1) and (2). See *fillet weld*.

Toggle Press

A *mechanical press* in which the *slide* is actuated by one or more toggle links or mechanisms.

Tolerance

The specified permissible deviation from a specified nominal dimension or the permissible variation in size or other quality characteristic of a part.

Tolerance Limits

The extreme values (upper and lower) that define the range of permissible variation in size or other quality characteristic of a part. See also *quality characteristics*.

Tomographic Plane

A section of the part imaged by the tomographic process. Although in computed tomography the tomographic plane or slice is displayed as a 2D image, the measurements are of the materials within a defined slice thickness associated with the plane. See also *slice* and the term *computed tomography*.

Tomography

From the Greek “to write a slice or section.” The process of imaging a particular plane or slice through an object. See also *computed tomography*.

Tonghold

The portion of a forging billet, usually on one end, that is gripped by the operators tongs. It is removed from the part at the end of the forging operation. Common to drop hammer and press-type forging.

Tool Set

See *die*.

Tool Side

The side of a plastic part that is cured against the tool (mold or mandrel).

Tool Steel

To develop their best properties, tool steels are always heat treated. Because the parts may distort during heat treatment, precision parts should be semifinished, heat treated, and then finished. Severe distortion is most likely to occur during liquid quenching, so an alloy should be selected that provides the needed mechanical properties with the least severe quench.

Steels are used primarily for cutters in machining, shearing, sawing, punching, and trimming operation, and for dies, punches, and molds in cold- and hot-forming operations. Some are also occasionally used for nontool applications. Tool steels are primarily ingot-cast wrought products, although some are now also powder-metal products. Regarding powder-metal products, there are two kinds: (1) mill products, mainly bar, produced by consolidating powder into “ingot” and reducing the ingot by conventional thermomechanical wrought techniques, and (2) end product tools, produced directly from powder by pressing and sintering techniques. There are seven major families of tool steels as classified by the American Iron and Steel Institute: (1) high-speed tool steels, (2) hot-work tool steels, (3) cold-work tool steels, (4) shock-resisting tool steels, (5) mold steels, (6) special-purpose tool steels, and (7) water-hardening tool steels.

High-Speed Tool Steels

These steels are subdivided into three principal groups or types: the molybdenum type, designated M1–M46, the tungsten type (T1–T15), and the intermediate molybdenum type (M50–M52). Virtually all M-types, which contained 3.75%–9.5% molybdenum, also contain 1.5%–6.75% tungsten, 3.75%–4.25% chromium, 1%–3.2% vanadium, and 0.85%–1.3% carbon. M33–M46 also contain 5%–8.25% cobalt, and M6, 12% cobalt. The T-types, which are molybdenum-free, contain 12%–18% tungsten, 4%–4.5% chromium, 1%–5% vanadium, and 0.75%–1.5% carbon. Except for T1, which is cobalt-free, they also contain 5%–12% cobalt.

Both M50 and M52 contain 4% molybdenum and 4% chromium; the former also contain 0.85% carbon and 1% vanadium, the latter 0.9% carbon, 1.25% tungsten, and 2% vanadium.

The molybdenum types are now by far the most widely used, and many of the T-types have M-type counterparts. All of the high-speed tool steels are similar in many respects. They all can be hardened to at least Rockwell C63, have fine-grain size, and deep-hardening characteristics. Their most important feature is hot hardness; they all can retain a hardness of Rockwell C52 or more at 538°C. The M-types, as a group, are somewhat tougher than the T-type at equivalent hardness but otherwise mechanical properties of the two types are similar. Cobalt improves hot hardness, but at the expense

T

of toughness. Wear resistance increases with increasing carbon and vanadium contents. The M-types have a greater tendency to decarburization and, thus, are more sensitive to heat treatment, especially austenitizing. Many of the T-types, however, are also sensitive in this respect, and they are hardened at somewhat higher temperatures. The single T-type that stands out is T-15, which is rated as the best of all high-speed tool steels from the standpoint of hot hardness and wear resistance. Typical applications for both the M-type and T-type include lathe tools, end mills, broaches, chasers, hobs, milling cutters, planar tools, punches, drills, reamers, routers, taps, and saws. The intermediate M-types are used for what somewhat similar cutting tools but, because of their lower alloy content, are limited to less-severe operating conditions.

Hot-Work Tool Steels

These steels are subdivided into three principal groups: (1) the chromium type (H10–H19), (2) the tungsten type (H21–H26), and (3) the molybdenum type (H42). All are medium-carbon (0.35%–0.60%) grades. The chromium types contain 3.25%–5.00% chromium and other carbide-forming elements, some of which, such as tungsten and molybdenum, also impart hot strength, and vanadium, which increases high-temperature wear resistance. The tungsten types, with 9%–18% tungsten, also contain chromium, usually 2%–4%, although H23 contains 12% of each element. Tungsten hot-work tool steels with higher contents of alloying elements are more heat resistant at elevated temperatures than H11 and H13 chromium hot-work steels, but the higher percentage also tends to make them more brittle in heat treating.

The one molybdenum type, H42, contains slightly more tungsten (6%) than molybdenum (5%), and 4% chromium and 2% vanadium. These alloying elements (chromium, molybdenum, tungsten, and vanadium) make the steel more resistant to heat checking than tungsten hot-work steels. Also, their lower carbon content in relation to high-speed tool steels gives them a higher degree of toughness.

Typical applications include dies for forging, die casting, extrusion, heading, trim, piercing and punching, and shear blades.

Cold-Work Tool Steels

There are also three major groups of cold-work tool steels: (1) high carbon (1.5%–2.35%); high chromium (12), which are designated D2–D7; (2) medium alloy air-hardening (A2–A10), which may contain 0.5%–2.25% carbon, 0%–5.25% chromium, 1%–1.5% molybdenum, 0%–4.75% vanadium, 0%–1.25% tungsten, and, in some cases, nickel, manganese or silicon, or nickel and manganese; and (3) oil-hardening types (O1–O7). They are used mainly for cold-working operations, such as stamping dies, drawing dies, and other forming tools as well as for shear blades, burnishing tools, and coining tools.

Shock-Resistant Tool Steels

These steels (S1 to S7) are, as a class, the toughest, although some chromium-type hot-work grades, such as H10–H13, are somewhat better in this respect. The S-types are medium-carbon (0.45%–0.55%) steels containing only 2.50% tungsten and 1.50% chromium (S1), only 3.25% chromium and 1.40% molybdenum (S7), or other combinations of elements, such as molybdenum and silicon, manganese and silicon, or molybdenum, manganese, and silicon. Typical uses include chisels, knockout pins, screwdriver blades, shear blades, punches, and riveting tools.

Mold Steels

There are three principal mold steels: (1) P6, containing 0.10% carbon, 3.5% nickel, and 1.5% chromium; P20, 0.35% carbon, 1.7% chromium, and 0.40% molybdenum; and P21, 0.20% carbon, 4% nickel, and 1.2% aluminum. P6 is basically a carburizing steel produced to tool-steel quality. It is intended for hubbing—producing die cavities by pressing with a male plug—then carburizing, hardening, and tempering. P20 and P21 are deep-hardening steels and may be supplied in hardened condition. P21 may be carburized and hardened after machining. These steels are tough but low in wear resistance and moderate in hot hardness; P21 is best in this respect. All three are oil-hardening steels, and they are used mainly for injection and compression molds for forming plastics, but they also have been used for die-casting dies.

Special-Purpose Tool Steels

These steels include L2, containing 0.50%–1.10% carbon, 1.00% chromium, and 0.20% vanadium; and L6, having 0.70% carbon, 1.5% nickel, 0.75% chromium, and, sometimes, 0.25% molybdenum. L2 is usually hardened by water quenching and L6, which is deeper hardening, by quenching in oil. They are relatively tough and easy to machine and are used for brake-forming dies, arbors, punches, taps, wrenches, and drills.

Water-Hardening Tool Steels

Water-hardening tool steels include W1, which contains 0.60%–1.40% carbon and no alloying elements; W2, with the same carbon range and 0.25% vanadium; and W5, having 1.10% carbon and 0.50% chromium. All are shallow-hardening and the least qualified of tool steels in terms of hot hardness. However, they can be surface-hardened to high hardness and, those provide high resistance to surface wear. They are the most readily machined tool steels. Applications include blanking dies, cold-striking dies, files, drills, counter sinks, taps, reamers, and jewelry dies.

Coatings

To prolong tool life, tool steel end products, such as mills, hobs, drills, reamers, punches, and dies, can be nitrided or coated in several ways. Oxide coatings, imparted by heating to about 566°C in a steam atmosphere or by immersing in aqueous solutions of sodium hydroxide and sodium nitrite at 140°C, are not as effective as traditional nitriding but do reduce friction and adhesion between the workpiece and the tool. The thickness of the coating developed in the salt bath is typically less than 0.005 mm, and its nongalling tendency is especially useful for operations at which failure occurs this way. Hard-chromium plating to a thickness of 0.0025–0.0127 mm provides a hardness of DPH 950–1050 and is more effective than oxide coating, but the plate is brittle and, thus, not advisable for tools subject to shock loads. Its toughness may be improved somewhat without substantially reducing wear resistance by tempering at temperatures below 260°C, but higher tempering temperatures impair hardness, thus wear resistance, appreciably. An antiseize iron sulfide coating can be applied electrolytically at 191°C using sodium and potassium thiocyanate. Because of the low temperature, the tools can be coated in the fully hardened and tempered condition without affecting hardness. Tungsten carbide is another effective coating. One technique, called Rocklinizing, deposits 0.0025–0.0203 mm of carbide using a vibrating arcing electrode of the material in a handheld gun. Titanium carbide and titanium nitride are the latest coatings. Nitride, typically 0.008 mm thick, has stirred the greatest interest, although carbide may have advantages for press tools

subject to high pressure. In just the past few years, all sorts of tools, primarily cutters but also dies, have been titanium nitride-coated, which imparts a gold- or brass-like look. The coating can be applied by chemical vapor deposition (CVD) at 954°C–1066°C or by physical vapor deposition (PVD) at 482°C or less. Thus, the PVD process has an advantage in that the temperature involved may be within or below the tempering temperature of the tool steels so that the coating can be applied to fully hardened and tempered tools. Also, the risk of distortion during coating is less.

Another method being used to prolong tool life is to subject the tools to a temperature of –196°C for about 30 h. The cryogenic treatment, which has been called Perm-O-Bond and Cryo-Tech, is said to rid the steel of any retained austenite—thus the improved tool life.

Properties

Toughness

Toughness in *tool steels* is best defined as the ability of a material to absorb energy without fracturing rather than the ability to deform plastically without breaking. Thus, a high elastic limit is required for best performance since large degrees of flow or deformation are rarely permissible in fine tools or dies. Hardness of a tool has considerable bearing on the toughness because the elastic limit increases with an increase in hardness. However, at very high hardness levels, increased notch sensitivity and brittleness are limiting factors.

In general, lower carbon tool steels are tougher than higher carbon tool steels. However, shallow hardening carbon (W-1) or carbon–vanadium (W-2) tool steels with a hard case and soft core will have good toughness regardless of carbon content. The higher alloy steels will range between good and poor toughness depending upon hardness and alloying content.

Abrasion Resistance

Some tool steels exhibit better resistance to abrasion than others. Attempts to measure absolute abrasion resistance are not always consistent, but in general, abrasion resistance increases as the carbon and alloy contents increase. Carbon is an influential factor. Additions of certain alloying elements (chromium, tungsten, molybdenum, and vanadium) balanced with carbon have a marked effect on increasing the abrasion resistance by forming extremely hard carbides.

Hardness

Maximum attainable hardness is primarily dependent upon the carbon content, except possibly in the more highly alloyed tool steels. Tool steels are generally used somewhat below maximum hardness except for deep-drawing dies, forming dies, coating tools, etc. Battering or impact tools are put in service at moderate hardness levels for improved toughness.

Hot Hardness

The ability to retain hardness with increasing temperature is defined as hot hardness or red hardness. This characteristic is important in steels used for hot-working dies. Generally, as the alloy content of the steel is increased (particularly in chromium, tungsten, cobalt, molybdenum, and vanadium, which form stable carbides), the resistance to softening at elevated temperatures is improved. High-alloy tool steels with a properly balanced composition will retain a high hardness up to 593°C. In the absence of other data, hardness after high-temperature tempering will indicate the hot hardness of a particular alloy.

Heat Treatment

Hardenability

Carbon tool steels are classified as shallow hardening, that is, when quenched in water from the hardening (austenitizing) temperature, they form a hardened case and a soft core. Increasing the alloy content increases the hardenability or depth of hardening of the case. A small increase in alloy content will result in a steel that will harden through the cross sections when quenched in oil. If the increase in alloy content is great enough, the steels will harden throughout when quenched in still air. For large tool or die sections, a high-alloy tool steel should be selected if strength is to be developed throughout the section in the finished part.

For carbon tool steels that are very shallow in hardening characteristics, the P/F test, Disc test, and PV test are methods for rating this characteristic. Oil-hardening tool steels of medium-alloy content are generally rated for hardenability by the Jominy End Quench test.

Dimensional Changes during Heat Treatment

Carbon tool steels are apt to distort because of the severity of the water quench required. In general, water-hardening steels distort more than oil hardening, and oil hardening distort more than air-hardening steels. Thus, if a tool or die is to be machined very close to the final size before heat treatment and little or no grinding is to be performed after treatment, an air-hardening tool steel would be the proper selection.

Resistance to Decarburization

During heat treatment, steels containing large amounts of silicon, molybdenum, and cobalt tend to lose carbon from the surface more rapidly than steels containing other alloying elements. Steels with extremely high carbon content are also susceptible to rapid decarburization. Extra precautions should be employed to provide a neutral atmosphere when heat treating these steels. Otherwise, danger of cracking during hardening will be present. Also, it would be necessary to allow a liberal grinding allowance for cleanup after heat treatment.

Machinability

Since most tool steels, even in the annealed state, contain wear-resistant carbides, they are generally more difficult to machine than the open-hearth grades or low-alloy steels. In general, the machinability tends to decrease with increasing alloying content. Microstructure also has a marked effect on machinability. For best machinability, a spheroidal microstructure is preferred over pearlitic.

The addition of small amounts of lead or sulfur to the steels to improve machinability has gained considerable acceptance in the tool steel industry. These free machining steels not only machine more easily but also give a better surface finish than the regular grades. However, some caution is advised in applications involving transverse loading since lead or sulfur additions actually add longitudinal inclusions in the steel.

Available Forms

Tool steels are available in billets, bars, rods, sheets, and coil. Special shapes can be furnished upon request. Generally, the material is furnished in the soft (or annealed) condition to facilitate machining. However, certain applications require that the steel be cold-drawn or prehardened to a specified hardness.

A word of caution: Mill decarburization is generally present on all steel except that guaranteed by the producer to be

T

decarburization-free. It is important that all decarburized areas be removed prior to heat treating or the tool or die may crack during hardening.

Tooling

A generic term applied to die assemblies and related items used for forming and forging metals.

Tooling Marks

Indications imparted to the surface of the forged part from dies containing surface imperfections or dies on which some repair work has been done. These marks are usually slight rises or depressions in the metal.

Tooling Resin

Resins that have applications as tooling aids, coreboxes, prototypes, hammer forms, stretch forms, foundry patterns, and so forth. Epoxy and silicone are common examples.

Tooth

(1) A projection on a multipoint tool (such as on a saw, milling cutter, or file) designed to produce cutting. (2) A projection on the periphery of a wheel or segment thereof—as on a gear, spline, or sprocket, for example—designed to engage another mechanism and thereby transmit force or motion, or both. A similar projection on a flat member such as a rack.

Tooth Point

On a *face mill*, the chamfered cutting edge of the blade, in which a flat is sometimes added to produce a shaving effect and to improve finish.

Top-and-Bottom Process

A process for separating copper and nickel, in which their molten sulfides are separated into two liquid layers by the addition of sodium sulfide. The lower layer holds most of the nickel.

Top Hat Furnace

See *Bell Furnace*.

Top Pouring

The normal process of pouring molten metal into the mold from the top. This allows solidification to commence at the bottom and has the advantage of simplicity. However, it has the disadvantage that it may induce turbulence, splashing, erosion of the mold, and entrainment of dross.

Topaz

The naturally occurring mineral, aluminum fluorosilicate, $\text{Al}_2\text{F}_2\text{SiO}_4$, having various colors depending on the individual impurities. It is hard and is No. 8 on the Mohs scale.

Torch

See *blowpipe*, *cutting torch*, and *welding torch*.

Torch Brazing

A soldering process in which the heat required is furnished by a fuel gas flame.

Torch Tip (Brazing)

That part of an oxyfuel gas brazing torch from which the gases issue. See also *cutting tip* and *welding tip*.

Toroid

Doughnut-shaped piece of magnetic material, together with one or more coils of current-carrying wire wound about the doughnut, with the permeability of the magnetic material high enough so that the magnetic flux is almost completely confined within it. Also known as *toroidal coil* and *toroidal magnetic circuit*.

Torque

The force of rotation, the product of force and the perpendicular distance between the axis of rotation and the direction of the force.

Torque-Coil Magnetometer

A magnetometer that depends for its operation on the torque developed by a known current in a coil that can turn in the field to be measured. See also *magnetometer*.

Torr

A non SI unit of pressure used for measuring near vacuum conditions. 1 torr = 1 mm Hg = 133.322 Pa.

Torsion

- (1) A twisting deformation of a solid or tubular body about an axis in which lines that were initially parallel to the axis become helices.
- (2) A twisting action resulting in shear stresses and strains.

Torsional Moment

In a body being twisted, the algebraic sum of the couples or the moments of the external forces about the axis of twist, or both.

Torsional Pendulum

A device for performing dynamic mechanical analysis of plastics, in which the sample is deformed torsionally and allowed to oscillate in free vibration. Modulus is determined by the frequency of the resultant oscillation, and damping is determined by the decreasing amplitude of the oscillation.

Torsional Stress

The shear stress on a transverse cross section caused by a twisting action.

Torsion Test

A test designed to provide data for the calculation of the *shear modulus*, *modulus of rupture in torsion*, and *yield strength* and shear yield.

Torsion Twisting

The state of strain induced by torque.

Total Carbon

The sum of the *free carbon* and *combined carbon* (including carbon in solution) in a ferrous alloy.

Total Cyanide

Cyanide content of an electroplating bath (including both simple and complex ions).

Total Elongation

The total amount of permanent extension of a test piece broken in a tensile test usually expressed as a percentage over a fixed gauge length. See also *elongation, percent*.

Total-Extension-Under-Load Yield Strength

See *yield strength*.

Total Indicator Reading

See *total indicator variation*.

Total Indicator Variation

The difference between the maximum and minimum indicator readings during a checking cycle.

Total Transmittance

The ratio of the radiant energy leaving one side of a region between two parallel planes to the radiant energy entering from the opposite side.

Touch Welding

Metal arc welding in which the tip of the coating on the consumable electrode remains in contact with the parent metal during the welding operation. The electrode has a coating formulated to form a cup standing around the metal core during welding to avoid core to parent contact.

Toughness

Ability of a material to absorb energy and deform plastically before fracturing. Toughness is proportional to the area under the *stress-strain curve* from the origin to the breaking point. In metals, toughness is usually measured by the energy absorbed in a notch impact test. See also *impact test*.

An imprecise term encompassing the capacity to absorb energy prior to and during the cracking process, to deform plastically without

cracking and to resist crack growth. It implies resistance to impact and hence the results of impact test may be referred to as “toughness.” A measure of toughness is also provided by the area under the curve plotted from a tensile test. Also see *fracture toughness*.

Tough Pitch Copper

Copper containing from 0.02% to 0.04% oxygen, obtained by refining copper in a reverberatory furnace. See *copper*.

Tow

An untwisted bundle of continuous filaments, usually referring to man-made fibers, particularly carbon and graphite, but also fiberglass and aramid. A tow designated as 140 K has 140,000 filaments.

T-Peel Strength

The average load per unit width of adhesive bond line required to produce progressive separation of two bonded, flexible adherends, under standard test conditions.

TPI

See *thermoplastic polyimides*.

TPUR

See *thermoplastic polyurethanes*.

Tracer

In composites fabrication, fiber, tow, or yarn added to a prepreg for verifying fiber alignment and, in the case of woven materials, for distinguishing warp fibers from fill fibers.

Tracer Milling

Duplication of a three-dimensional form by means of a cutter controlled by a tracer that is directed by a master form.

Tracer Techniques

The use of small quantities of radioactive materials to monitor processes such as corrosion, wear, diffusion, and pollution.

Track

The mark made by a seal on the surface with which it mates.

Tracking

The breakdown of electrical resistance via a narrow track across a surface of an insulator. It usually results from some external contamination.

Tracking Pattern

The path a seal ring makes when in rubbing contact with the mating ring or seal plate.

T

Traction

In rolling contacts, the tangential stress transmitted across the interface. The traction will in general vary from point to point over the contact area. More generally, traction may denote the force per unit area of contact.

Tractive Force

The integral of the tangential surface stress over the area of contact.

Traditional Ceramics

Traditional ceramics are generally classified as those ceramic products that use clay or have a significant clay component in the batch. A clay-based ceramic body usually consists of one or more clays or clay minerals mixed with nonclay mineral powders such as fluxes (for example, feldspar) and fillers (for example, silica and alumina). Each of these constituents contributes to the plastic forming and fired characteristics of the body, with the clay acting as a plasticizer and binder for the other constituents.

Commercial clays are grouped as being kaoline (China) clay or ball clay. Kaolines consist primarily of ordered kaolinite, $\text{Al}_2\text{Si}_2\text{O}_5(\text{OH})_4$, with some mica and free quartz. Ball clays, which are dug out of the ground in “blocks” or “balls,” tend to be very fine grained and are composed of ordered and disordered kaolinite and varying percentages of mica, illite, montmorillonite, free quartz, and organic matter.

Traditional ceramic bodies are formed into shapes using many different techniques. A general sequence of unit operations would include raw material preparation, batch preparation, forming, drawing, prefire operations (glazing, decorating, etc.), firing, and post-fire operations (glazing, decorating, machining, and/or cleaning). Forming techniques include hand molding and pottery wheels, extrusion, die pressing, and *slip casting*.

The five principal product areas for traditional ceramics are whitewares, glazes and porcelain enamels, structural clay products, cement, and refractories. Whiteware is the name given to a group of ceramic products characterized by a white or light-colored body with a fine-grained structure. Most whiteware products are glazed or decorated with patterns or designs. Examples of whiteware products are sanitary ware, tableware, artware, stoneware, and floor and wall tile.

A glaze is defined as a continuous adherent layer of glass on the surface of a ceramic body that is hard, nonabsorbent, and easily cleaned. A glaze is usually applied as a suspension of glaze-forming ingredients in water. After the glaze layer dries on the surface of the piece, it is fired, whereupon the ingredients melt to form a thin layer of glass. Porcelain enamels are very durable alkali borosilicate glass coatings bonded by fusion to metal substrates at temperatures above 425°C. Porcelain enamels are applied primarily to steel sheet, cast iron, aluminum alloys (in sheet or cast form), and aluminum-coated steels. See also the term *porcelain enamel*.

Structural clay products are ceramic materials used in construction. The raw materials are naturally occurring clays or shales. A distinguishing manufacturing characteristic of structural clays is their exposure to elevated firing temperatures to develop a bond between the particulate constituents and to develop the desired pore structure (pore quality, pore size distribution, and pore connection) for the intended application. Structural clay products include facing materials for buildings, building brick, paving brick, roofing tile, sewer pipe, and drain tile.

Cements are inorganic powders consisting predominantly of calcium silicates, which, when mixed with water to form a paste,

react slowly at ambient temperatures to produce a coherent, hardened mass with valuable engineering properties. The hardened powder product is porous and consists primarily of calcium silicate hydrate. Uses of cement include steel-reinforced pipe, panels, columns, and beams, highway pavements, foundations, canal linings, dams, bridges decks, and floor slabs. See also *cement*.

Refractories are construction materials that can withstand high temperatures and maintain their physical properties. They are used extensively in structures associated with iron and steel production, copper and aluminum smelting, and glass and ceramic manufacturing. The primary types of clay refractories are fireclay and high alumina. Each type is used to produce bricks, as well as insulating refractories. See also *refractories*.

Traffic Mark

See *abrasion*.

Tramp Alloys

Residual alloying elements that are introduced into steel when unidentified alloy steel is present in the scrap charge to a steelmaking furnace.

Tramp Element

Contaminant in the components of a furnace charge, or in the molten metal or castings, whose presence is thought to be either unimportant or undesirable to the quality of the casting. Also called trace element.

Tramp Materials

Any contaminating materials entrained in a process and undesirable because they might enter the product or damage the production equipment.

Transcrystalline/Granular

Running across the crystal/grain, for example, a crack running fully or partly across a grain rather than around the grain boundary. Compare with intragranular that refers to features such as precipitates within a grain. See *transgranular*.

Transducer

A material capable of converting electrical energy to mechanical energy or vice versa.

Transfer

In tribology, the process by which material from one sliding surface becomes attached to another surface, possibly as a result of interfacial adhesion. Transfer is usually associated with adhesion, but the possibility of mechanical interlocking adherence, without adhesive bonding, exists in certain occurrences. The material may also back transfer to the surface from which it came. See also *selective transfer*.

Transfer Ladle

A ladle that can be supported on a monorail or carried in a shank and used to transfer metal from the melting furnace to the holding furnace or from the furnace to the pouring ladles.

Transfer Molding

A method of molding thermosetting materials in which the plastic is first softened by heat and pressure in a transfer chamber and then forced by high pressure through suitable sprues, runners, and gates into a closed mold for final shaping and curing. See also *resin transfer molding*.

Transference

The movement of ions through the *electrolyte* associated with the passage of the electric current. Also called transport or migration.

Transference Number

The proportion of total electroplating current carried by ions of a given kind. Also called transport number.

Transferred Arc

A plasma arc established between the electrode and the workpiece during plasma arc welding, cutting, and thermal spraying. See also the term *nontransferred arc* and *plasma welding*.

Transformation

Change from one phase to another at the transformation temperature.

Transformation Hardening

Heat treatment of steels comprising austenitization followed by cooling under conditions such that the austenite transforms more or less completely into martensite and possibly into bainite.

Transformation-Induced Plasticity

A phenomenon, occurring chiefly in certain highly alloyed steels that have been heat treated to produce metastable austenite or metastable austenite plus martensite, whereby, on subsequent deformation, part of the austenite undergoes strain-induced transformation to martensite. Steels capable of transforming in this manner, commonly referred to as TRIP steels, are highly plastic after heat treatment, but exhibit a very high rate of strain hardening and thus have high tensile and yield strengths after plastic deformation at temperatures between about 20°C and 500°C. Cooling to -195°C may or may not be required to complete the transformation to martensite. Tempering usually is done following transformation.

Transformation Ranges

Those ranges of temperature without which austenite forms during heating and transforms during cooling. The two ranges are distinct, sometimes overlapping but never coinciding. The limiting temperatures of the ranges depend on the composition of the alloy and on the

rate of change of temperature, particularly during cooling. See also *transformation temperature* and *steel*.

Transformation Temperature

The temperature at which a change in phase occurs. This term is sometimes used to denote the limiting temperature of a transformation range. The following symbols are used for irons and steels:

A_{cm}: In a hypereutectoid steel, the temperature at which solution of cementite in austenite is completed during heating.

A_{c1}: The temperature at which austenite begins to form during heating.

A_{c3}: The temperature at which transformation of ferrite to austenite is completed during heating.

A_{c4}: The temperature at which austenite transforms to delta ferrite during heating.

A_{cm}, A_{e1}, A_{e3}, A_{e4}: The temperatures of phase changes at equilibrium.

A_{r_{cm}}: In hypereutectoid steel, the temperature at which precipitation of cementite starts during cooling.

A_{r1}: The temperature at which transformation of austenite to ferrite or to ferrite plus cementite is completed during cooling.

A_{r3}: The temperature at which austenite begins to transform to ferrite during cooling.

A_{r4}: The temperature at which delta ferrite transforms to austenite during cooling.

A_r: The temperature at which transformation of austenite to pearlite starts during cooling.

M_r: The temperature at which transformation of austenite to martensite is completed during cooling.

M_s (or A_r''): The temperature at which transformation of austenite to martensite starts during cooling.

Note: All these changes, except formation of martensite, occur at lower temperatures during cooling than during heating and depend on the rate of change of temperature.

Transformation-Toughened Zirconia

A generic term applied to stabilized zirconia systems in which the tetragonal symmetry is retained as the primary zirconia phase. The four most popular tetragonal phase stabilizers are ceria (CeO₂), calcia (CaO), magnesia (MgO), and yttria (Y₂O₃). See also *zirconia*.

Transformed Beta

A local or continuous structure in titanium alloys consisting of decomposition products arising by nucleation and growth processes during cooling from above the local or overall β transus. Primary and regrowth α may be present. Transformed β typically consists of α platelets that may or may not be separated by β phase.

Transformer Steel

Steel having low magnetic hysteresis, and hence used as sheet for the laminations of electrical transformers and generator stators. Such steels are typically very low carbon with 2%–5% silicon and are carefully cold rolled to maximize their magnetic characteristics.

T

Transgranular

Through or across crystals or grains. Also called intracrystalline or transcrystalline.

Transgranular Cracking

Cracking or fracturing that occurs through or across a crystal or grain. Also called transcrystalline cracking. Contrast with *intergranular cracking*. See the term step fracture (metals) (1).

Transgranular Fracture

Fracture through or across the crystals or grains of a material. Also called transcrystalline fracture or intracrystalline fracture. Contrast with *intergranular fracture*.

Transient Creep

See *creep* and *primary creep*.

Transistor

An active semiconductor device capable of providing power amplification and having three or more terminals.

Transitional Fit

A fit that may have either clearance or interference resulting from specified tolerances on hole and shaft.

Transition Diagram

In tribology, a plot of two or more experimental or operating variables that indicates the boundaries between various regimes of wear or surface damage. The *IRG transition diagram* is a plot of normal force (ordinate) versus sliding velocity (abscissa) and is used to identify three regions with differing lubrication effectiveness. Various plots have been called transition diagrams, and the context of usage must be established.

Transition Elements

The elements, all metals, having an incomplete inner electron shell.

Transition Joint (Weld)

A weld formed between two different metals.

Transition Lattice

An unstable crystallographic configuration that forms as an intermediate step in a solid-state reaction such as precipitation from solid solution or eutectoid decomposition. See *phase change*.

Transition Metal

(1) A metal in which the available electron energy levels are occupied in such a way that the *d*-band contains less than its maximum number of ten electrons per atom, for example, iron, cobalt, nickel, and tungsten. The distinctive properties of the transition metals result from the incompletely filled *d*-levels. (2) The metallic

elements usually shown as a block in the periodic table between Groups II and III. They arise because their atomic structure includes incompletely “filled” inner subshells. See *atomic structure* and *periodic table*.

Transition Phase

A nonequilibrium state that appears in a chemical system in the course of transformation between two equilibrium states.

Transition Point

At a stated pressure, the temperature (or at a stated temperature, the pressure) at which two solid phases exist in equilibrium—that is, an allotropic transformation temperature (or pressure).

Transition Scarp

A *rib mark* generated when a crack changes from one mode of growth to another, as when a wet crack accelerates abruptly from Region II (plateau) to Region III (dry) of a crack acceleration curve. See also *intersection scarp*.

Transition Structure

In precipitation from solid solution, a metastable precipitate that is coherent with the matrix.

Transition Temperature

(1) The temperature at which the properties of a material change. Depending on the material, the transition change may or may not be reversible. (2) Any temperature at which a transition occurs but in particular the temperature at which steel changes from ductile to brittle behavior. See also *fracture appearance transition temperature*.

Transition Temperature (Metals)

(1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as the ductile-to-brittle transition temperature (DBTT). The DBTT can be assessed in several ways, the most common being the temperature for 50% ductile and 50% brittle fracture (50% fracture appearance transition temperature, or FATT), or the lowest temperature at which the fracture is 100% ductile (100% fibrous criterion). The DBTT is commonly associated with *temper embrittlement* and *radiation damage* (neutron irradiation) of low-alloy steels. (2) Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.

Translation

The relative movement as one block of atoms slides across another.

Transmission Electron Microscope

A microscope in which the image-forming rays pass through (are transmitted by) the specimen being observed. Using the transmission

electron microscope, microstructural features can be imaged at 1000–450,000 $\times$. See *electron microscope*.

Transmission Electron Microscopy (TEM)

An analytical technique in which an image is formed on a cathode-ray tube whose raster is synchronized with the raster of an electron beam over an area of the sample surface. Image contrast is formed by the scattering electrons out of the beam. TEM is used for very high magnification characterization of metals, ceramics, metals, polymers, and biological materials.

Transmission Grating

In electron optics, a transparent diffraction grating through which light is transmitted. See also *concave grating*, *diffraction grating*, *plane grating*, and *reflection grating*.

Transmission Method

A method of x-ray or electron diffraction in which the recorded diffracted beams emerge on the same side of the specimen as the transmitted primary beam.

Transmission Oil

(1) Oil used for transmission of hydraulic power. (2) Oil used to lubricate automobile transmission systems.

Transmittance

The ratio of the light intensity transmitted by a material to the light intensity incident upon it. In emission spectrochemical analysis, the transmittance of a developed photographic emulsion, including its film or glass supporting base, is measured by a microphotometer. In absorption spectroscopy, the material is the sample. See also *diffuse transmittance*, *relative transmittance*, *specular transmittance*, and *total transmittance*.

Transpassive Region

The region of *anodic polarization curve*, noble to and above the passive *potential* range, in which there is a significant increase in current density (increased metal dissolution) as the potential becomes more positive (noble).

Transpassive State

(1) State of anodically passivated metal characterized by a considerable increase of the corrosion current, in the absence of pitting, when the *potential* is increased. (2) The noble region of potential where an electrode exhibits a higher than passive current density.

Transport

See *transference*.

Transport Number

Same as *transference* number.

Trans Stereoisomer

A stereoisomer in which atoms or groups of atoms are arranged on opposite sides of a chain of atoms. See also *isotactic stereoisomerism*.

Transuranic/Transuranium Elements

The man-made elements having an atomic number greater than 92, that of uranium.

Transverse Direction

Literally, “across,” usually signifying a direction or plane perpendicular to the direction of working. In rolled plate or sheet, the direction across the width is often called long transverse; the direction through the thickness, short transverse.

Transverse Resistance Seam Welding

The making of a resistance seam weld in a direction essentially at right angles to the throat depth of a resistance seam welding machine. See also the term *resistance seam welding*. Contrast with *longitudinal resistance seam welding*.

Transverse Rolling Machine

Equipment for producing complex preforms or finished forgings from round billets inserted transversely between two or three rolls that rotate in the same direction and drive the billet. The rolls, carrying replaceable die segments with appropriate impressions, make several revolutions for each rotation of the workpiece.

Transverse Rupture Strength

The stress, as calculated from the flexure formula, required to break a sintered powder metallurgy specimen. The test for determining the transverse rupture strength involves applying the load at the center of a 31.8 by 12.7 by 6.4 mm beam, which is supported near its ends.

Transverse Strain

The linear strain in a plane perpendicular to the loading access of a specimen.

Transverse Test (Bend, Tension, etc.)

A test across the primary axis of the material or across the line of a weld.

Transversely Isotropic

(1) In reference to a material, exhibiting a special case of orthotropy in which properties are identical in two orthotropic dimensions but not the third. (2) Having identical properties in both transverse (short and long) but not in the longitudinal direction.

Trapped-Sheet, Contact Heat, Pressure Thermoforming

A *thermoforming process* for making plastic parts in which a hot, porous blow plate is used in both heating and forming processes.

T

The plastic sheet lies between the female mold cavity and the hot blow plate. Air forced through the plate and pressure from the female mold push the sheet onto the hot plate. When the sheet is sufficiently heated, air pressure forces it into the female mold.

Travel Angle

The angle that a welding electrode makes with a reference line perpendicular to the axis of the weld in the plane of the weld axis. This angle can be used to define the position of welding guns, welding torches, high-energy beams, welding rods, thermal cutting and thermal spraying torches, and thermal spraying guns. See also *drag angle* and *push angle* and the term *backhand welding* and *forehand welding*.

Travel Angle (Pipe)

The angle that a welding electrode makes with a reference line extending from the center of the pipe through the molten weld pool in the plane of the weld axis.

Traverse Speed

The lineal velocity at which the torch is passed across the substrate during the thermal spraying operation.

Treeing

Localized excessive deposition of electroplate due to high current density in the area.

Trees

Visible projections of electrodeposited metal formed at sites of high current density.

Trepanning

(1) A machining process for producing a circular hole or groove in solid stock, or for producing a disk, cylinder, or tube from solid stock, by the action of a tool containing one or more cutters (usually single-point) revolving around a center. (2) Boring a hole by cutting away only a narrow circumferential band rather than the full cross section. This releases a central core assuming that the process is completed to the far surface.

Triaxiality

In a *triaxial stress* state, all stresses being tensile.

Triaxial Stress

A state of stress in which none of the three principal stresses is zero. See also *principal stress (normal)*.

Tribo

A prefix indicating a relationship to interacting surfaces in relative motion.

Tribochemistry

The part of chemistry dealing with interacting surfaces in relative motion. Tribochemistry broadly encompasses such areas as lubricant chemistry, changes in reactivity of surfaces due to mechanical contact, oxidative wear, and other phenomena.

Triboelement

A solid body that is bounded by one or more *tribosurfaces* and that resides within a *tribosystem*. For example, in a pin-on-disk tribosystem, the pin is one triboelement and the disk is another. See the term *pin-on-disk machine*.

Tribology

(1) The science and technology of interacting surfaces in relative motion and of the practices related thereto. (2) The science concerned with the design, friction, lubrication, and the wear of contacting surfaces that move relative to each other (as in bearings, cams, or gears, for example).

Tribometer

(1) An instrument or testing rig to measure normal and frictional forces of relatively moving surfaces. (2) Any device constructed for or capable of measuring the friction, lubrication, and wear behavior of materials or components.

Tribophysics

That part of physics dealing with interacting surfaces in relative motion.

Triboscience

The scientific discipline devoted to the systematic study of interacting surfaces in relative motion. Triboscience includes the scientific aspects of *tribochemistry*, *tribophysics*, contact mechanics, and materials and surface sciences as related to *tribology*.

Tribosurface

Any solid surface whose intermittent, repeated, or continuous contact with another surface or surfaces, in relative motion, results in friction, wear, and/or surface damage. The surface of a body subjected to a catastrophic collision would not generally be considered a tribosurface because significant damage to the entire body is involved.

Tribosystem

Any functional combination of *triboelements*, including thermal and chemical surroundings.

Tribotechnology

The aspect of *tribology* that involves the engineering application of *triboscience* and the design, development, analysis, and repair of components for tribological applications.

Trichloroethylene

A volatile, nonflammable hydrocarbon used as a solvent and degreasant.

Triclinic

Having three axes of any length, none of the included angles being equal to one another or equal to 90°.

Tridymite

An allotrope of quartz. See *quartz*.

Triggered Capacitor Discharge

A high-voltage electrical discharge used in *emission spectroscopy* for vaporization and excitation of a sample material. The energy for the discharge is obtained from capacitors that are charged from an ac or dc electrical supply. Each discharge may be either oscillatory, critically damped, or overdamped. It is initiated by separate means and is extinguished when the voltage across the analytical gap falls to a value that no longer is sufficient to maintain it.

Trimetal Bearing

A bearing consisting of three layers. Trimetal bearings are often made of bronze with a white metal facing and a steel backing. See the term *sleeve bearing*.

Trimmer

The dies used to remove the flash or excess stock from a forging.

Trimmer Blade

The portion of the trimmers through which a forging is pushed to shear off the flash.

Trimmer Die

The punch press die used for trimming flash from a forging.

Trimmer Punch

The upper portion of the trimmer that contacts the forging and pushes it through the trimmer blades; the lower end of the trimmer punch is generally shaped to fit the surface of the forging against which it pushes.

Trimmers

The combination of *trimmer punch*, *trimmer blades*, and perhaps *trimming shoe* used to remove the flash from the forging.

Trimming

(1) In forging, removing any parting-line flash or excess material from the part with a trimmer in a trim press; can be done hot or cold. (2) In drawing, shearing the irregular edge of the drawn part. (3) In casting, the removal of gates, risers, and fins.

Trimming Press

A power press suitable for trimming flash from forgings.

Trimming Shoe

The holder used to support *trimmers*. Sometimes called trimming chair.

Triple-Action Press

A mechanical or hydraulic press having three slides with three motions properly synchronized for triple-action drawing, redrawing, and forming. Usually, two slides—the blankholder slide and the plunger—are located above and a lower slide is located within the bed of the press. See also *hydraulic press*, *mechanical press*, and *slide*.

Triple Curve

In a *P-T diagram*, a line representing the sequence of pressure and temperature values along which two conjugate phases occur in univariant equilibrium.

Triple Point

(1) A point on a phase diagram where three phases of a substance coexist in equilibrium. (2) The intersection of the boundaries of three adjoining grains, as observed in a metallographic section.

Tripoli

A name given to finely granulated, white, porous, siliceous rock, used as an abrasive and as a filler. True tripoli is an infusorial, diatomaceous earth known as **tripolite**, and is a variety of opal, or **opaline silica**. In the abrasive industry, it is called **soft silica**.

The material marketed for oil-well drilling mud under the name of **Opalite**, is an amorphous silica. Tripoli is used in massive form for the manufacture of filter stones for filtering small supplies of water and is also used for the manufacture of foundry parting. Finely ground tripoli, free from iron oxide, is used as a paint roller and in rubber. Tripoli grains are soft, porous, and free from sharp cutting faces, and they give a fine polishing effect. It is the most commonly used polishing agent. The word **silex**, which is an old name for silica and is also used to designate the pulverized flint from Belgium, is sometimes applied to finely ground white tripoli employed as an inert filler for paints. It is used with oil on rag-wheel polishing. A 250-mesh powder is used as a filler in molding compounds.

TRIP Steel

A commercial steel product exhibiting *transformation-induced plasticity*.

Trisodium Phosphate

A white, crystalline substance also known as **phosphate cleaner**, used in soaps, cleaning compounds, plating, textile processing, and boiler compounds. The commercial grade is not less than 97% pure, with total alkalinity of 16%–19%. The anhydrous trisodium phosphate is 2.3 times as effective as the crystalline form but requires a longer time to dissolve. **Disodium phosphate** is a white, crystalline product used for weighting silk, boiler treatment, cheese making, and cattle feeds.

T

The medicinal, or USP, grade has only seven molecules of water and has a different crystal structure. The commercial grade is 99.4% pure and is readily soluble in water. **Trisodium phosphate hemihydrate** is a granular, crystalline grade for degreasing and water conditioning. Monosodium phosphate is made by reacting soda ash with phosphoric acid in molecular proportions; it is used in similar applications to the disodium variety. **Sodium tripolyphosphate** is a water-soluble, white powder used as a detergent, a water softener, and a deflocculating agent in portland cement to govern the viscosity of the shale slurry without excessive use of water. Large quantities of these phosphates are used in the processing of chemicals, textiles, and paper; and since they are toxic contaminants of ground and surface waters, mill waste must be deactivated before they are discharged. The use of phosphates in detergents and soap powders has been banned in many areas since they lead to rapid algae growth in surface waters.

Tritium

Hydrogen with three neutrons in the nucleus. See *atomic structure*.

Triton

The nucleus of tritium (^3H), the triton is the only known radioactive nuclide belonging to hydrogen and β -decays to ^3He with a half-life of 12.4 years.

Trommel

A revolving cylindrical screen used in grading coarsely crushed ore.

Tropenas Converter

A converter in which air, possibly oxygen enriched, is blown from the side across the charge of previously desulfurized molten pig iron and scrap. The process is used for steel castings of lower quality.

Troy Ounce

A unit of weight for *precious metals* that is equal to 31.1034768 g (1.0971699 avoirdupois).

True Current Density

See preferred term *local current density*.

True Rake

See preferred term *effective rake*.

True Strain

(1) The ratio of the change in dimension, resulting from a given load increment, to the magnitude of the dimension immediately prior to applying the load increment. (2) In a body subjected to axial force, the natural logarithm of the ratio of the gage length at the moment of observation to the original gage length. Also known as natural strain.

True Stress

The value obtained by dividing the load applied to a member at a given instant by the cross-sectional area over which it acts. See *tensile test*.

Truing

The removal of the outside layer of abrasive grains on a grinding wheel for the purpose of restoring its face.

Trumpet Alloy

A brass with about 20% zinc, 1% tin, remainder copper, used for musical instruments.

Trunnion Bearing

A bearing used as a pivot to swivel or turn an assembly.

Tryout

In metal forming or forging, a preparatory run to check or test equipment, lubricant, stock, tools, or methods prior to a production run. Production tryout is run with tools previously approved; new die tryout is run with new tools not previously approved.

T.S.N.

Thermal severity number. See *controlled thermal severity test*.

T.T.T.

See *time-temperature-transformation diagrams*.

Tube

A pipe or hollow section. The various terms are largely interchangeable but "tube" would usually indicate a fairly small diameter and a simple cross section.

Tube Furnace

A furnace used for continuous or batch sintering powder metallurgy parts that utilizes a dense ceramic tube or a metallic retort to contain the controlled sintering atmosphere.

Tube Making

The basic tube making sequences can be categorized as

- Piercing and subsequent processes
- Welding of rolled sheet or plate
- Extrusion

These are described briefly in the succeeding text.

Piercing sequences commence with hot piercing, followed by hot reducing and cold reducing. In the press piercing process, a heated cylindrical billet, usually set in a die, has a tool forced along the central axis to fully penetrate the billet or nearly so. Alternatively, the billet may be fully pierced in a barrel or Mannesmann rotary piercer. This comprises a pair of barrel-shaped rolls set not quite parallel and rotating in the same direction. The heated billet is introduced, end on, into the end gap of the rolls. The rotation of the rolls spins the billet, and their angled alignment draws it in. At the same time, the barrel taper compresses the spinning billet across the diameter,

which tends to open up a zone of weakness at the billet center line. A piercing point carried on a mandrel is located part way along the roll gap to coincide with the zone of weakness and the forward motion then thrusts the weak end center over the point to form the tube. The disc or Stiefel piercer processes are similar in concept except that the rolls are mushroom shaped and set with their axes near parallel but displaced. The three-roll piercing process is again similar to the Mannesmann mill except that three rolls are used, the central weak zone is less pronounced, and the billet is effectively forced over the piercing point. Fully pierced billets are usually termed “blooms” or “hollows” and near pierced billets are termed “bottles.”

After piercing, the bloom is hot reduced by processes that include *hot rolling*, the *push bench* and the *pilger mill* or *rotary forge*, and *Assel mill* process. In hot rolling, the blooms or bottles are passed through grooved, driven rollers usually with a mandrel set in the bore to provide support and to control its size. The push bench process is usually applied to bottles. Immediately after piercing and without further heating, the bottle is set on a mandrel to be pushed through a series of dies and or nondriven rolls of progressively reducing diameter. The pilger mill comprises a pair of rolls with deep tapered grooves. The rolls have parallel axes and run in opposite directions with their faces in contact so that as the rolls rotate, the pair of grooves form, at the contact line, an orifice of varying diameter. The rolls rotate continuously and, when the orifice diameter is at its maximum, the heated bloom, carried on a mandrel, is thrust forward into the rolls against the direction of rotation. The rolls then force the tube backward, and the taper on the rolls forges a small length of the tube reducing its exterior diameter. This sequence is repeated with the tube being rotated 90° on each forward movement, and the tube moves progressively through the mill. The Assel mill is similar in layout to the Mannesmann piercer except that three rolls are deployed and they usually have a step at midlength to forge the heated bloom, carried on a mandrel, with better dimensional control than can be achieved by the pilger mill.

Cold reducing is commonly achieved by a drawing process in which the tube is pulled through a die. Usually, the bore is controlled by a mandrel or by a plug located in the tube bore at a position coinciding with the die. Drawing without use of a mandrel or plug is termed “sinking.” Multiple drawing passes may be made with, if necessary, interstage annealing. An alternative is the *cold-reducing process*, also termed the “rockrite process,” which is similar in concept to the pilger described earlier in that it uses tapered grooved rolls to produce a forging action. However, in this case, the groove diameter is much smaller in proportion to the roll size, and the pair of rolls reciprocates along a track changing rotation direction at the extremities of each stroke. The tube, on a tapered mandrel, is fed in at the point of maximum opening at the end of a stroke. It is not pushed backward by the rolls but is rotated slightly at each forward step to produce an even product. Large reductions of external diameter, bore, and wall thickness can be achieved with good control of dimensions including eccentricity.

Welded tube is produced from rolled sheet or plate, cut to width, and rolled into the tubular form and then welded. The seam is usually longitudinal but may be spiral. Virtually, any forms of welding can be employed depending upon the tube size and application but for higher quality tubing and smaller size ranges electrical resistance welding is popular. See also *extrusion* as this is a common route for tube production. Often extruded tube receives no further working, but in some cases, one or more drawing passes may be required.

Tube Manipulation

Various processes applied to tube ends.

Tube Plate

The perforated plate into which the tubes of a heat exchanger are sealed by some process such as expanding, welding, or soldering.

Tube Reducing

Reducing both the diameter and wall thickness of tubing with a mandrel and a pair of rolls. See also *spinning*.

Tube Sinking

Drawing tubing through a die or passing it through rolls without the use of an interior tool (such as a mandrel or plug) to control inside diameter; sinking generally produces a tube of increased wall thickness and length.

Tube Stock

A semifinished tube suitable for subsequent reduction and finishing.

Tuberculation

The formation of *localized corrosion* products scattered over the surface in the form of knoblike mounds called tubercles. The formation of tubercles is usually associated with *biological corrosion*.

Tubular Products, Steel

The general term used to cover all hollow carbon and low-alloy steel products used as conveyors of fluids and as structural members. Although these products are usually produced in cylinder form, they are often subsequently altered by various processing methods to produce square, oval, rectangular, and other symmetrical shapes.

Tumble Grinding

Various surfacing operations ranging from deburring and polishing to honing and microfinishing metallic parts before and after plating.

Tumbling

A process in which components are enclosed in a rotating barrel with some other material. The other material may be an abrasive, polishing or plating agent or peening shot—hence terms such as *tumble polishing*, *tumble peening*, and *tumble plating*. If both plating and peening agents are included, the process may be termed “peen plating.”

Tumbling (Metals)

Rotating workpieces, usually castings or forgings, in a barrel partly filled with metal slugs or abrasives, to remove sand, scale, or fins. It may be done dry or with an aqueous solution added to the contents of the barrel. See also *barrel finishing*.

Tumbling (Plastics)

Finishing operation for small plastic articles by which gates, flash, and fins are removed and/or surfaces are polished by rotating them in a barrel with wooden pegs, sawdust, and polishing compounds.

T

Tungsten and Alloys

In many respects, tungsten (symbol W) is similar to molybdenum. The two metals have about the same electrical conductivity and resistivity, coefficient of thermal expansion, and about the same resistance to corrosion by mineral acids. Both have high strength at temperatures above 1093°C, but because the melting point of tungsten is higher, it retains significant strength at higher temperatures than molybdenum does. The elastic modulus for tungsten is about 25% higher than that of molybdenum, and its density is almost twice that of molybdenum. All commercial unalloyed tungsten is produced by powder-metallurgy methods; it is available as rod, wire, plate, sheet, and some forged shapes. For some special applications, vacuum-arc-melted tungsten can be produced, but it is expensive and limited to relatively small sections.

Fabrication

Fabrication is a multistep process that converts tungsten metal from the original massive state (bars or ingots) to a more useful shape (sheet, tube, wire) and, at the same time, improves its physical properties. The exact details of fabrication depend on the method used for consolidating the metal and the type of product desired. Arc- or electron-beam-melted tungsten normally is extruded or forged to increase its ductility, whereas powder-processed material, because of its finer-grained structure and smaller tendency to crack, is less likely to require this initial step.

Tungsten is usually worked below its recrystallization temperature because the recrystallized metal tends to be brittle. Because increased working decreases the recrystallization temperature, successive lower temperatures are used in each fabrication step.

Full-density wrought tungsten can be hot forged, swaged, extruded, rolled, and drawn as secondary fabrication steps used to produce the final shape. Working temperature is usually 1100°C or above depending on the grain size and type of deformation.

Sintered billets are forged, swaged, or rolled initially at temperatures in excess of 1400°C. Working temperature can be progressively lowered as the amount of work increases, but consideration must be given to equipment capacity because of the high strength of tungsten.

Several tungsten alloys are produced by liquid-phase sintering of compacts of tungsten powder with binders of nickel-copper, iron-nickel, iron-copper, or nickel-cobalt-molybdenum combinations; tungsten usually comprises 85%–95% of the alloy by weight. These alloys are often identified as heavy metals or machinable tungsten alloys. In compact forms, the alloys can be machined by turning, drilling, boring, milling, and shaping; they are not available in mill products forms because they are unable to be wrought at any temperature.

Properties

Tungsten, element 74 on the periodic chart, has a melting point of approximately 3410°C, with values ranging between 3387°C and 3422°C reported in the literature. This value easily makes it the highest-melting-point metal. It has the lowest coefficient of thermal expansion of all metals, and with a density of 19.25 g/cm³, it is one of the heaviest. It has the lowest vapor pressure of all metals, and high thermal and electrical conductivity.

Single crystals of tungsten are elastically isotropic and have very high tensile and bulk moduli, but mechanical properties are strongly temperature dependent, with the yield strength and ultimate tensile

strength decreasing significantly with increasing temperature. At elevated temperatures, tungsten reacts rapidly with oxygen, forming a series of oxides that have stoichiometries ranging between WO₂ and WO₃.

The unique properties of tungsten make it the element of choice for such applications as filaments for incandescent lamps and x-ray tubes, electron sources for scanning and transmission electron microscopes, and connectors for circuit boards. Although these characteristics might suggest an even wider range of applications, several actually limit its utility. For example, the high density of tungsten makes it unsatisfactory for any weight-conserving application, and its aggressive reaction with oxygen limits its service at high temperatures. Welding is difficult because of the reactivity of tungsten with oxygen, and the presence of oxygen and other interstitials in the metal can make it very brittle at room temperature. Nonetheless, the special properties of tungsten are so beneficial that in many cases, it has been worth the cost and effort to engineer around the problems.

Tungsten retains a tensile strength of about 344 MPa at 1371°C, but because of its heavy weight is normally used in aircraft or missile parts only as coatings, usually sprayed on. It is also used for x-ray and gamma-ray shielding. Electroplates of tungsten or tungsten alloys give surface hardness to Vickers 700 or above.

Applications

Tungsten has a wide usage for alloy steels, magnets, heavy metals, electric contacts, rocket nozzles, and electronic applications. Tungsten resists oxidation at very high temperatures and is not attacked by nitric, hydrofluoric, or sulfuric acid solutions. Flame-sprayed coatings are used for nozzles and other parts subject to heat erosion.

Tungsten is usually added to iron and steel in the form of ferrotungsten, made by electric-furnace reduction of the oxide with iron or by reducing tungsten ores with carbon and silicon. Standard grades with 75%–85% tungsten have melting points from 1760°C to 1899°C. Tungsten powder is usually in sizes from 200 to 325 mesh and maybe had in a purity of 99.9%. Parts, rods, and sheet are made by powder metallurgy, and rolling and forging are done at high temperature.

The tungsten powder is used for spray coatings for radiation shielding and for powder-metal parts. Tungsten wire is used for spark plugs and electronic devices. Tungsten wire as fine as 0.00046 cm is used in electronic hardware. Tungsten whiskers, which are extremely fine fibers, are used in copper alloys to add strength. Copper wire, which normally has a tensile strength of 206 MPa, will have a strength of 827 MPa when 35% of the wire is tungsten whiskers. Tungsten yarns are made up of fine fibers of the metal. The yarns are flexible and can be woven into fabrics. Continuous tungsten filaments, usually 10–15 μm in diameter, are used for reinforcement in metal, ceramic, and plastic composites. Finer filaments of tungsten are used as cores, or substrates, for boron filaments.

The metal was also produced as arc-fused grown crystals, usually no larger than 0.952 cm in diameter and 25.4 cm long, and worked into rod, sheet, strip, and wire. Tungsten crystals, 99.9975% pure, are ductile even at very low temperatures, and wire as fine as 0.008 cm and strip as thin as 0.013 cm can be cold-drawn and cold-rolled from the crystal. The crystal metal has nearly zero porosity, and its electrical and heat conductivity are higher than ordinary tungsten.

One tungsten-aluminum alloy is a chemical compound made by reducing tungsten hexachloride with molten aluminum.

Tungsten wire is not used exclusively for lamp filaments. Because of its high melting temperature, tungsten can be heated to the point where it becomes a thermionic emitter of electrons, without losing

its mechanical integrity. Consequently, tungsten filaments are often used as electron sources in scanning electron microscopes and transmission electron microscopes, and also as filaments in x-ray tubes.

In x-ray tubes, electrons produced from the tungsten filament are accelerated so that they strike a tungsten or tungsten-rhenium anode, which emits the x-rays. Again, this application takes advantage of the high melting point of tungsten, since the energy of the electron beam required to generate x-rays is very high, and the spot where the beam hits the surfaces becomes very hot. In most tubes, the anode is rotated to limit the peak temperature and to allow for cooling.

Finally, tungsten filaments of a much larger size are often selected as the heating elements in vacuum furnaces. Again, because of the high melting point of tungsten, these furnaces can achieve much higher temperatures than furnaces made with other heating elements. It is important to note that in vacuum furnaces, as well as all of the other applications, the tungsten is in a controlled environment that inhibits its oxidation.

For example, tungsten heavy alloys are materials in which tungsten powder is liquid-phase sintered, usually with the nickel-iron powders, to produce a composite material in which tungsten occupies about 95% of the volume. As the sintering process proceeds, the nickel-iron powder melts. Although the solubility of liquid nickel-iron in solid tungsten is small, solid tungsten readily dissolves in liquid nickel-iron. As the liquid wets the tungsten particles and dissolves part of the tungsten powder, the particles change shape, and internal pores are eliminated as the liquid flows into them. As processing continues, the particles coalesce and grow, producing a final product that is approximately 100% dense and has an optimized microstructure.

One of the main products made by this method is kinetic energy penetrators of military armored vehicles. This application takes advantage of the high density of tungsten, and it has been found that the liquid sintered materials have better impact properties than pure tungsten made by traditional powder processing.

Cutting tools and parts that must resist severe abrasion are often made of tungsten carbide. Tungsten carbide chips or inserts, with the cutting edges ground, are attached to the bodies of steel tools by brazing or by screws. The higher cutting speeds and longer tool life made feasible by the use of tungsten carbide tools are such that the inserts are discarded after one use.

Tungsten compounds (5% of tungsten consumption) have a number of industrial applications. Calcium and magnesium tungstates are used as phosphors in fluorescent lights and television tubes. Sodium tungstate is employed in the fireproofing of fabrics and in the preparation of tungsten-containing dyes and pigments used in paints and printing inks. Compounds such as WO_3 and WS_2 are catalysts for various chemical processes in the petroleum industry. Both WS_2 and WSe_2 are dry, high-temperature lubricants. Other applications of tungsten compounds have been made in the glass, ceramics, and tanning industries.

A completely new and different approach to produce bulk tungsten products from the powder-metallurgy process is through chemical vapor deposition (CVD), which provides a tungsten coating on a substrate.

Tungsten hexafluoride is the most common tungsten source for CVD processing. This compound is a liquid at room temperature, but its vapor pressure is high enough that the vapor can be continuously extracted and passed across the part that is to be coated.

The reaction requires temperatures above approximately 300°C and a surface that causes the dissociation of molecular hydrogen into

atomic hydrogen. Therefore, sections of a part may be selectively coated by having surfaces that either catalyze or prevent this reaction.

One of the most important applications of this process has been in the electronics industry, in which tungsten vias are placed in integrated circuits. The vias are small metal plugs that connect one level of wiring to another in the circuit board. They are generally about 0.4 mm in diameter, with an aspect ratio of about 2.5. In future applications, the diameter may shrink to less than 0.1 mm and have an aspect ratio greater than five. The metal for this application must have good electrical conductivity, must not react with the surrounding materials, must adhere to the wiring or silicon above or below the via, and must be deposited by a CVD reaction, as that is the only way to fill such small holes.

The most important method in the electronics industry is blanket CVD. In this technology, an adhesive layer is first put down to make certain that the CVD tungsten will stick to the surface. This adhesive layer is often titanium nitride, TiN. Tungsten is deposited on top of this layer, covering the surface and filling the vias. After the CVD is complete, the tungsten on the entire surface is removed by chemical-mechanical polishing. This procedure leaves the vias filled but cleans the surface of the unnecessary tungsten.

Alloys

A large number of tungsten-based alloys have been developed. Binary and ternary alloys of molybdenum, niobium, and tantalum with tungsten are used as substitutes for the pure metal because of their superior mechanical properties. Adding small amounts of other elements such as titanium, zirconium, hafnium, and carbon to these alloys improves their ductility. Tungsten-rhenium alloys possess excellent high-temperature strength and improved resistance to oxidation but are difficult to fabricate. This problem is ameliorated somewhat by the addition of molybdenum, a common composition being W (40 at%)-Re (30%)-Mo (30%). The strengths of tungsten or tungsten-rhenium systems can be increased by small amounts of a dispersed second phase such as an oxide (ThO_2 , Ta_2O_5), carbide (HfC , TaC), or boride (HfB , ZrB). The so-called heavy alloys are three-component systems composed mainly of tungsten in combination with a nickel-copper or nickel-iron matrix. These materials are characterized by high density (17–19 g/cm³), hardness, and good thermal conductivity.

Tungsten is used widely as a constituent in the alloys of other metals, since it generally enhances high-temperature strength. Several types of tool steels and some stainless steels contain tungsten. Heat-resistant alloys, also termed “superalloys,” are nickel-, cobalt-, or iron-base systems containing varying amounts (typically 1.5–25 wt%) of tungsten. Wear-resistant alloys having the trade name Stellites are composed mainly of cobalt, chromium, and tungsten.

Cobalt-tungsten alloy, with 50% tungsten, gives a plate that retains a high hardness at red heat. Tungsten RhC is a tungsten-rhenium carbide alloy containing 4% rhenium carbide. It is used for parts requiring high strength and hardness at high temperatures. The alloy retains a tensile strength of 517 MPa at 1927°C.

Tungsten Carbide

Tungsten carbide is an iron-gray powder of minute cubical crystals with a Mohs hardness above 9.5 and a melting point of about 2982°C. It is produced by reacting a hydrocarbon vapor with tungsten at high temperature. The composition is WC, but at high heat, it may decompose into W_2C and carbon, and the carbide may be a mixture of the two forms. Other forms may also be produced, W_3C

T

and W_3C_4 . Tungsten carbide is used chiefly for cutting tool bits and for heat- and erosion-resistant parts and coatings.

One of the earliest of the American bonded tungsten carbides was *Carboloy*, which was used for cutting tools, gauges, drawing dies, and wear parts. The carbides are now often mixed carbides. Carboloy 608 contains 83% chromium carbide, 2% tungsten carbide, and 15% nickel binder. It is lighter in weight than tungsten carbide, is non-magnetic, and has a hardness to Rockwell A93. It is used for wear-resistant parts and resists oxidation to 1092°C. Titanium carbide is more fragile but may be mixed with tungsten carbide to add hardness for dies. *Kennametal K601* is used for seal rings and wear parts and is a mixture of tantalum and tungsten carbides without a binder. It has a compressive strength of 4650 MPa, rupture strength of 689 MPa, and Rockwell hardness A94. *Kennametal K501* is tungsten carbide with a platinum binder for parts subject to severe heat erosion.

Tungsten carbide LW-1 is tungsten carbide with about 6% cobalt binder used for flame-coating metal parts to give high-temperature wear resistance. Deposited coatings have a Vickers hardness to 1450 and resists oxidation at 538°C. *Tungsten carbide LW-1N*, with 15% cobalt binder, as a much higher rupture strength, but the hardness is reduced to 1150.

Tungsten Electrode

A nonfiller metal electrode used in arc welding or cutting, made principally of tungsten. See *welding torch (arc)*.

Tungsten Filaments

Thin tungsten wire used principally in incandescent lamps and other filament applications that require resistance to creep at high temperatures.

Tungsten Inert Gas Welding

Welding in which the electric arc is struck between the component being welded and a nonconsumable tungsten electrode, and the weld zone is shielded by a gas that is inert during the welding operation. See *gas tungsten arc welding*.

Tungsten Steel

Tungsten steel is any steel containing tungsten as the alloying element imparting the chief characteristics to the steel. It is one of the oldest of the alloying elements in steel.

Tungsten increases the hardness of steel and gives it the property of red hardness, stabilizing the hard carbides at high temperatures. It also widens the hardening range of steel and gives deep hardening. Very small quantities serve to produce a fine grain and raise the yield point. The tungsten forms a very hard carbide and an iron tungstite, and the strength of the steel is also increased, but it is brittle when the tungsten content is high. When large percentages of tungsten are used in steel, they must be supplemented by other carbide-forming elements. Tungsten steels, except the low-tungsten chromium–tungsten steels, are not suitable for construction, but they are widely used for cutting tools, because the tungsten forms hard abrasion-resistant particles in high-carbon steels. Tungsten also increases the acid resistance and corrosion resistance of steels. The steels are difficult to forge and cannot be readily welded when tungsten exceeds 2%. Standard tungsten–chromium alloy steels 72XX contain 1.5%–2% tungsten and 0.50%–1% chromium. Many tool steels rely on tungsten as an alloying element, and it may range from 0.50% to 2.50% in cold-work and shock-resistant types to 9%–18% in the hot-work type, and 12%–20% in high-speed steels.

Tup

The moving head of a forge, in particular a drop forge.

Tup Impact Test

A falling-weight (tup) impact test developed specifically for plastic pipe and fittings.

Turbine Oil

An oil used to lubricate bearings in a steam or gas turbine.

Turk's Head Rolls

Four undriven working rolls, arranged in a square or rectangular pattern, through which metal strip, wire, or tubing is drawn to form square or rectangular sections.

Turning

(1) Removing material by forcing a single-point cutting tool against the surface of a rotating workpiece. The tool may or may not be moved toward or along the axis of rotation, while it cuts away a material. (2) A machining operation in which the workpiece is gripped in the chuck of a lathe and rotated against a tool bit, which cuts away a material.

Turnings

The swarf, that is, strands or chips of metal removed by turning.

Turns Per Inch

In composites, a measure of the amount of twist produced in a *yarn*, *toe*, or *roving* during its processing history. See also *twist*.

Turpentine

Also called in the paint industry *oil of turpentine*. An oil obtained by steam distillation of the oleoresin, which exudes when various conifer trees are cut. Longleaf pine and slash pine are the main sources.

Wood turpentine, called in the paint industry *spirits of turpentine*, is obtained from waste wood, chips, or sawdust by steam extraction or by destructive distillation. Wood turpentine forms more than 10% of all American commercial turpentines. Wood turpentine has a peculiar characteristic sawmill odor, and the residue of distillation has a camphor-like odor different from that of gum turpentine. It differs very little in competition, however, from the true turpentine. Steam-distilled wood turpentine contains about 90% terpenes, of which 80% is alpha pinene and 10% is a mixture of beta pinene and camphene. Some wood turpentine is produced as a by-product in the manufacture of cellulose.

Turpentine varies in composition according to the species of pine from which it is obtained. It is produced chiefly in the United States, France, and Spain.

American turpentine oil boils at 154°C, and the specific gravity is 0.860. It is a valuable drying oil for paints and varnishes, owing to its property of rapidly absorbing oxygen from the atmosphere and transferring it to the linseed or other drying oil, which leaves a tough and durable film of paint. Turpentine is also used in the manufacture of artificial camphor and rubber, and in linoleum, soap, and ink. *Gum thus*, used in artists' oil paints, is thickened turpentine, although gum thus was originally made from olibanum. Turpentine is often adulterated

with other oils of the pine or with petroleum products, and the various states have laws regulating its adulteration for paint use.

Camphene is produced by isomerizing the alpha pinene of turpentine. Camphor is then produced by oxidation of camphene in acid. Camphene was also the name of a lamp oil of the early nineteenth century made from distilled turpentine and alcohol. It gave a bright white light but was explosive.

Turquoise

An opaque-blue gemstone with a waxy luster. It is a hydrous phosphate of aluminum and copper oxides. It is found in the western United States in streaks in volcanic rocks, but most of the turquoise has come from the Kuh-i-Firouzeh, or turquoise mountain, of Iran, which is a vast deposit of feldspar igneous rock. The valuable stones are the deep blue. The pale blue and green stones were called *Mecca stones* because they were sent to Mecca for sale to pilgrims. *Bone turquoise* or *odontolite*, used for jewelry, is fossil bone or tooth, colored by a phosphate of iron.

Tuyere

An opening in a cupola, blast furnace, or converter for the introduction of air or inert gas. See *blast furnace* and *cupola*.

Twill Weave

A basic fabric weave for reinforced plastics characterized by a diagonal rib or twill line. Each end floats over at least two consecutive picks, allowing a greater number of yarns per unit area than in a plain weave, while not losing a great deal of fabric stability. See also *plain weave*.

Twin

(1) Two portions of a crystal with a definite orientation relationship; one may be regarded as the parent, the other as the twin. The orientation of the twin is a mirror image of the orientation of the parent across a twinning plane or an orientation that can be derived by rotating the twin portion about a twinning axis. (2) An arrangement of the crystal lattice in which the planes of atoms on adjacent blocks in a crystal are aligned in a mirror image of each other. Under the microscope, the intersection between the blocks appears as a line. Annealing twins can occur during annealing of metals have a face-centered cubic structure. In this case, the individual twin lines in a pair are straight, run from grain boundary to grain boundary, and may be well separated. Mechanical twins can be formed during working of body-centered cubic and close-packed hexagonal structures. Microscopically, these twins appear within a grain as a pair of closely spaced, curved lines joined at their ends in a lenticular formation. Mechanical twins, formed in steel failing in a brittle manner, usually as a result of shock loading, are termed Neumann bands or Neumann lamellae. See also the *annealing twin* and *mechanical twin*.

Twin Bands

Bands across a crystal grain, observed on a polished and etched section, where crystallographic orientations have a mirror-image relationship to the orientation of the matrix grain across a composition plane that is usually parallel to the sides of the band.

Twin Carbon Arc Brazing

A brazing process that produces coalescence of metals by heating them with an electric arc between two carbon electrodes. The filler metal is distributed in the joint by capillary action.

Twin Carbon Arc Welding

A *carbon arc welding* process variation that produces coalescence of metals by heating them with an electric arc between two carbon electrodes. No shielding is used. Pressure and filler metal may or may not be used.

Twin-Sheet Thermoforming

A technique for *thermoforming* hollow plastic objects by introducing high-pressure air between two sheets and blowing the sheets into the mold halves (vacuum is also applied).

Twist

(1) In a yarn or other textile strand, the spiral turns about its axis per unit of length. Twist may be expressed as *turns per inch (tpi)*. Twist provides additional integrity to yarn before it is subjected to the weaving process, a typical twist consisting of up to one turn per inch. In many instances, heavier yarns are needed for the weaving operation. This is normally accomplished by twisting together two or more single strands, followed by a plying operation. Plying essentially involves retwisting the twisted strands in the opposite direction from the original twist. The two types of twist normally used are known as S and Z, which indicate the direction in which the twisting is done. Usually, two or more strands twisted together with an S twist are plied with a Z twist in order to give a balanced yarn. Thus, the yarn properties, such as strength, bundle diameter, and yield, can be manipulated by the twisting and plying operations. (2) In pultruded parts, twist describes a condition of longitudinal, progressive rotation that can be easily detected for a noncircular cross-section by placing the pultrusion on a plane surface, holding one end flat with the surface, and observing whether one edge or side of the other end does not lie parallel with that surface.

Twist Boundary

The subgrain boundary consisting of an array of screw *dislocations*.

Twist Drill

A drill bit with a pair of cutting edges formed by the junction of the helical flutes and the conical tip. The function of the flutes is to lead away the swarf as the drill penetrates.

Twist Hackle (Ceramics and Glasses)

A *hackle* that separates portions of the crack surface, each of which has rotated from the original crack plane in response to a twist in the axis of principal tension. In a single crystal, a twist hackle separates portions of the crack surface, each of which follows the same cleavage plane, the normal to the cleavage plane being inclined to the principal tension. In a bicrystal or polycrystalline material, a hackle is initiated at a twist grain boundary.

T

Two-Component Adhesive

An adhesive supplied in two parts that are mixed before application. Such adhesives usually cure at room temperature.

Two-High Mill

A type of rolling mill in which only two rolls, the working rolls, are contained in a single housing. Compare with *four-high mill* and *cluster mill*.

T-X Diagram

A 2D graph of the isobaric phase relationships in a binary system; the coordinates of the graph are temperature and concentration.

Type Metal

Any of a series of alloys containing lead (58.5%–95%), antimony (2.5%–25%) used to make printing type. Small amounts of copper (1.5%–2.0%) are added to increase hardness in some applications.

Any metal used for making printing type, but the name generally refers to *lead–antimony–tin* alloys. Antimony has the property of expanding on cooling and thus fills the mold and produces sharp, accurate type. The properties required in a type metal are ability to make sharp, uniform castings strength and hardness, fairly low melting point, narrow freezing range to facilitate rapid manufacture in type-making machines, and resistance to dressing. A common type metal is composed of nine parts lead to one antimony, but many

varieties of other mixtures are also used. The antimony content may be as high as 30%, 15%–20% being frequent. A common *monotype metal* has 72% lead, 18% antimony, and 10% tin. Larger and softer types are made of other alloys, sometimes containing bismuth; the hardest small type contains three parts lead to one antimony. A low melting point, soft-type metal contains 22% bismuth, 50% lead, and 28% antimony. It will melt at about 154°C. Copper, up to 2%, is sometimes added to type metal to increase the hardness but is not ordinarily used in metals employed in rapid-acting type machines. Some monotype metal has about 18% antimony, 8% tin, and 0.1% copper, but standard *linotype metal* for pressure casting has 79% lead, 16% antimony, and 5% tin. *Stereotype metal*, for sharp casting and hard-wearing qualities, is given as 80.0% lead, 13.5% antimony, 6% tin, and 0.5% copper. *Intertype metal* has 11%–14% antimony and 3%–5% tin. A typical formula for *electrotype metal* is 94% lead, 3% tin, and 3% antimony. The Brinell hardness of machine-molded type ranges from 17 to 23, and that of stereotype metal is up to 30. As constant remelting causes the separation of the tin and lead, and the loss of tin, or impoverishment of the metal, new metal must be constantly added to prevent deterioration of a standard metal into an inferior alloy. For many years, lead–antimony–tin alloys have been used as a weld seam filler in auto and truck bodies. In this application, they are commonly referred to as *body solder*. Because of advances in printing technology and auto manufacturing, use of these lead alloys is steadily declining. See *white metal* and *Babbitt metal*.

Typical Basis

An average property value. No statistical assurance is associated with this basis

U-Bend Die

A die, commonly used in pressure-break forming, that is machined horizontally with a square or rectangular cross-sectional opening that provides two edges over which metal is drawn into a channel shape.

Ugine-Séjournet Process

A direct extrusion process for metals that uses molten glass to insulate the hot billet and to act as a lubricant. Same as Séjournet process.

UHMWPE

See *ultrahigh-molecular-weight polyethylene*.

Ultimate Elongation

The elongation at rupture.

Ultimate Load (in Brinell Test)

The load that will just force the Brinell ball to a depth of half its diameter.

Ultimate Strength

The maximum strength (tensile, compressive, or shear) a material can sustain without fracture; determined by dividing maximum load by the original cross-sectional area of the specimen. Also known as nominal strength or maximum strength.

Ultimate Tensile Strength

The ultimate or final (highest) stress sustained by a specimen in a tension test. Same as *tensile strength*. See *tensile test*.

Ultrahard Tool Materials

Very hard, wear-resistant materials—specifically polycrystalline diamond and polycrystalline cubic boron nitride—that are fabricated into solid or layered cutting tool blanks for machining applications. See also *superabrasives*.

Ultrahigh-Molecular-Weight Polyethylene

Those polyethylene resins having weight-average molecular weights ranging from 3×10^6 to 6×10^6 . These materials have both the highest abrasion resistance and the highest impact strength of any plastic. See also *high-density polyethylenes*.

Ultrahigh-Strength Steels

These are the highest-strength steels available. Arbitrarily, steels with tensile strengths of around 1378 MPa or higher are included in

this category, and more than 100 alloy steels can be thus classified. They differ rather widely among themselves in composition or the way in which the ultrahigh strengths are achieved.

Medium-carbon low-alloy steels were the initial ultrahigh-strength steels, and within this group, a chromium–molybdenum steel (4130) grade and a chromium–nickel–molybdenum steel (4340) grade were the first developed. These steels have yield strengths as high as 1654 MPa and tensile strengths approaching 2068 MPa. They are particularly useful for thick sections because they are moderately priced and have deep hardenability. Several types of stainless steels are capable of strengths above 1378 MPa, including a number of martensitic, cold-rolled austenitic, and semiaustenitic grades. The typical martensitic grades are types 410, 420, and 431, as well as certain age-hardenable alloys. The cold-rolled austenitic stainless steels work-harden rapidly and can achieve 1241 MPa tensile yield strength and 1378 MPa ultimate strength. Semiaustenitic stainless steels can be heat treated for use at yield strengths as high as 1516 MPa and ultimate strengths of 1620 MPa.

Maraging steels contain 18%–25% nickel plus substantial amounts of cobalt and molybdenum. Some newer grades contain somewhat less than 10% nickel and between 10% and 14% chromium. Because of the low carbon (0.03% max) and nickel contents, maraging steels are martensitic in the annealed condition but are still readily formed, machined, and welded. By a simple aging treatment at about 482°C, yield strengths of as high as 2068 and 2413 MPa are attainable, depending on specific composition. In this condition, although ductility is fairly low, the material is still far from being brittle.

Among the strongest of plain carbon sheet steels are the low- and medium-carbon sheet grades called *MarTinsite*. Made by rapid water quenching after cold rolling, they provide tensile yield strengths of as high as 1517 MPa but are quite limited in ductility.

There are two types of ultrahigh-strength, low-carbon, hardenable steels. One, a chromium–nickel–molybdenum steel, named *Astralloy*, has 0.24% carbon and is air-hardened to a yield strength of 1241 MPa and heavy sections when it is normalized and tempered at 260°C. The other type is an iron–chromium–molybdenum–cobalt steel and is strengthened by a precipitation hardening and aging process to levels of up to 1654 MPa in yield strength. High-alloy quenched and tempered steels are another group that has extra-high strengths. They contain 9% nickel, 4% cobalt, and 0.20%–0.30% carbon and develop yield strengths close to 2068 MPa and ultimate strengths of 2413 MPa. Another group in this high-alloy category resembles high-speed tool steels but is modified to eliminate excess carbide, considerably improving ductility. These so-called matrix steels contain tungsten, molybdenum, chromium, vanadium, cobalt, and about 0.5% carbon. They can be heat treated to ultimate strengths of over 2757 MPa—one of the highest strengths achievable in steels, except for heavily cold-worked high-carbon steel strips used for razor blades and drawn wire for musical instruments, both of which have tensile strengths as high as 4136 MPa.

These steels have a high fracture toughness (K_{Ic} of 100 MPa√m, or 91 ksi√in).

U

Ultra Light Metals

See *light metals*.

Ultramicroscopic

See *submicroscopic*.

Ultrasonic

Sound waves at frequencies above those audible to the human ear. They are readily transmitted through solids and be used to detect subsurface defects. See *nondestructive testing*. They are also utilized in ultrasonic cleaning to clean components immersed in a bath of liquid, and in ultrasonic soldering, they disrupt the normally tenacious oxide film, such as that on aluminum, which would otherwise impede bonding between the underlying metal and the solder.

Ultrasonic Beam

A beam of acoustical radiation with a frequency higher than the frequency range for audible sound—that is, above about 20 kHz.

Ultrasonic Bonding

A method of joining plastics using vibratory mechanical pressure at ultrasonic frequencies. Electrical energy is changed to ultrasonic vibrations by means of either a magnetostrictive or piezoelectric transducer. The ultrasonic vibrations generate frictional heat, melting the plastics and allowing them to join.

Ultrasonic Cleaning

Immersion cleaning aided by ultrasonic waves that cause microagitation.

Ultrasonic Coupler

In ultrasonic welding and soldering, the elements through which ultrasonic vibration is transmitted from the transducer to the tip.

Ultrasonic C-Scan Inspection

A method for displaying the relative attenuation of ultrasonic waves across the surface of a structural component. An ultrasonic transducer is used to scan the surface of a material mechanically in than x - y raster scan mode while generating and receiving waves. Either the material is immersed in a water bath or columns of water are provided between the transducer and the material as a medium for ultrasonic energy transmissions. The received wave signals are electronically conditioned and measured to determine relative energy losses of the wave as it progresses through the material at each particular location on the specimen. Ultrasonic C-scan has been used extensively to determine both the initial integrity of a manufactured part and the void content and to follow the initiation and progression of damage resulting from environmental loading.

Ultrasonic Frequency

A frequency, associated with elastic waves, that is greater than the highest audible frequency, generally regarded as being higher than 20 kHz.

Ultrasonic Gas Atomization

A variation of the gas atomization process that uses high-frequency gas pulses with velocities up to 4,600 m/s (15,100 ft/s) to break up the molten metal stream. This process can produce high yields of powder with particle diameters less than 20 μ m.

Ultrasonic Impact Grinding

Material removal by means of an abrasive slurry and the ultrasonic vibration of a nonrotating tool. The abrasive slurry flows through a gap between the workpiece and the vibrating tool. Material removal occurs when the abrasive particles, suspended in the slurry, are struck on the downstroke of the vibrating tool. The velocity imparted to the abrasive particles causes microchipping and erosion as the particles impinge on the workpiece. See also *ultrasonic machining*.

Ultrasonic Inspection

A nondestructive method in which beams of high-frequency sound waves are introduced into materials for the detection of surface and subsurface flaws in the material. The sound waves travel through the material with some attendant loss of energy (attenuation) and are reflected at interfaces. The reflected beam is displayed and then analyzed to define the presence and location of flaws or discontinuities. Most ultrasonic inspection is done at frequencies between 0.1 and 25 MHz—well above the range of human hearing, which is almost 20 Hz–20 kHz.

Ultrasonic Machining

A process for machining hard, brittle, nonmetallic materials that involves the ultrasonic vibration of a rotating diamond core drill or milling tool. Rotary ultrasonic machining is similar to the conventional drilling of glass and ceramic with diamond core drills, except that the rotating core drill is vibrated at an ultrasonic frequency of 20 kHz. Rotary ultrasonic machining does not involve the flow of an abrasive slurry through a gap between the workpiece on the tool. Instead, the tool contacts and cuts the workpiece, and a liquid coolant, usually water, is forced through the bore of the tube to cool and flush away the removed material. See also *ultrasonic impact grinding*.

Ultrasonic Soldering

The soldering process variation in which high-frequency vibratory energy is transmitted through molten solder to remove undesirable surface films and thereby promote wetting of the base metal. This operation is usually accomplished without a flux.

Ultrasonic Testing

See *ultrasonic inspection*.

Ultrasonic Welding

A solid-state process in which materials are welded by locally applying high-frequency vibratory energy to a joint held together under pressure. Ultrasonic energy is produced through a transducer, which converts high-frequency electrical vibrations to mechanical vibrations at the same frequency, usually above 15 kHz (above the audible range). Mechanical vibrations are transmitted through a coupling

system to the welding tip and into the workpieces. The tip vibrates laterally, essentially parallel to the weld interface, while static force is applied perpendicular to the interface.

The vibration, typically in the range of 20–40 kHz, is generated electrically with available power of 200–3000 W and is delivered to the weld zone by the machine head, sometimes termed a *sonotrode*. An additional static interfacial force is normally applied, and additional external heating is an option. See the term *ultrasonic coupler*.

Ultraspeed Welding

See preferred term *commutator-controlled welding*.

Ultraviolet

Pertaining to the region of the electromagnetic spectrum from approximately 10 to 380 nm. The term ultraviolet without further qualification usually refers to the region from 200 to 380 nm.

Ultraviolet-Curable Hot-Melt Adhesives

For years, ultraviolet (UV)-curable pressure-sensitive adhesives (PSAs) have been recognized as a fixture alternatively to solvent-borne products. The idea of achieving the solvent and heat resistance of an acrylic without facing the various safety and environmental ramifications has always been enticing to both PSA formulators and users. The promise of this technology has led to the development of a variety of adhesive technology platforms.

Photoinitiators can now be purchased that offer much better thermal stability for improved pot life and coatability. Polymers have been developed that are much more chemically active, dramatically reducing the amount of photoinitiator required to achieve proper cure (and consequently the total cost of the adhesive). Thanks to the response of their suppliers, adhesive manufacturers are making UV-curable products that are more versatile than ever.

Converting a pressure-sensitive hot-melt coating line over to UV curing no longer demands growing accustomed to radically different adhesives.

Properties and Applications

Conventional hot-melt PSAs are widely used for tape and label applications. Their room temperature performance is difficult to match with alternative chemistries. They possess an outstanding combination of a high tack, peel, and shear and adhere well to wet on low-energy surfaces.

In addition to the performance advantages, conventional hot melts possess some significant processing advantages because they require no solvent vehicle for application. The lack of a combustible solvent makes them safer and more environmentally friendly than any other adhesive.

Because they require no drying, they can be applied more easily at high depositions for use on slick or rough surfaces. Finally, since they require no dryers, hot-melt coaters are generally more compact and lower in cost than liquid coaters.

Unfortunately, users of conventional hot melts can only enjoy these benefits over a limited range of conditions. The products are hobbled by poor resistance to solvents, plasticizers, and heat. This precludes their use in some industrial applications where their high room temperature peel and shear could make them otherwise well suited.

Types and Forms

Traditional pressure-sensitive hot melts are formulated primarily with block copolymers and various tackifying resins. The cohesive strength of the product is largely determined by the block copolymer used. Some of the most common block copolymers used are styrenic triblock copolymers. These are long polymer chains with polystyrene molecules grouped together to form two end blocks surrounding one midblock made of an elastomeric material. Frequently used triblock copolymers are styrene–isoprene–styrene or styrene–butadiene–styrene.

Future

UV offers an outstanding combination of versatile performance and ease of use. The UV-curable hot melt is comparable to the solvent-borne acrylic. In addition, a significant performance advantage has been seen on low-energy surfaces. This makes the technology even more appealing because of the ever-increasing use of plastics.

With new tools at their disposal, the performance of UV curables is now up to any adhesive task required. Formulators have crafted newer and better adhesives capable of a variety of tasks. These products capture the traditional advantages of hot melts while meeting many of the standards of acrylics.

Ultraviolet Degradation

The degradation caused by long-term exposure of a material to sunlight or other ultraviolet rays containing radiation.

Ultraviolet/Electron Beam Cured Adhesives

Radiation curing involves the rapid conversion of specially formulated, 100% reactive liquids to solids. Potential energy sources include microwaves, visible infrared (IR), ultraviolet (UV), and electron beam (EB) sources, the latter two being the most commercially important. Radiation-cured materials are used as coatings, inks, adhesives, sealants, and potting compounds.

The UV curing process typically involves the exposure of a reactive liquid that contains a photoinitiator to UV radiation at a wavelength between 200 and 400 nm. The liquid is rapidly converted to a solid, usually in less than 60 s. In the EB curing process, electrons are artificially generated and accelerated to energies of less than 100 keV to greater than 1 billion keV. Generally, 50–350 keV electrons are used to cure adhesives that have bond lines with thicknesses of 25–38 μm . The reactive liquid in the EB process does not contain a photoinitiator.

Because the main advantage of UV-/EB-curable adhesives is rapid curing at room temperature, they can be used to bond the heat-sensitive substrates, such as polyvinyl chloride. UV-/EB-cured adhesives have been used to replace solvent-base adhesives because of the increasing cost of properly recovering and disposing of solvents. The cross-linked nature of UV-/EB-cured adhesives results in good chemical, heat, and abrasion resistance; toughness; dimensional stability; and adhesion to many substrates. Unlike thermal curing, EB curing can be selective, and the depth of penetration can be controlled.

Most UV/EB adhesives are based on an addition polymerization curing mechanism. Materials consist of acrylic acid esters of various forms or combinations of acrylates with aliphatic or aromatic epoxies, urethanes, polyesters, or polyethers. Although the epoxy-base systems have higher tensile strengths, their elongations are less than those of the urethane-base systems. In addition, the urethane-base systems have better abrasion resistance.

U

Typical UV-curable adhesive applications include the electronics, automotive, medical, optics, and packaging markets, as well as tapes and labels. EB-curable adhesives are used in magnetic tapes and floppy disks, where magnetic particles are bonded to films, as well as in packaging, tapes, and labels.

Ultraviolet Radiation

Electromagnetic radiation in the wavelength range of 10–380 nm. See also *electromagnetic radiation*.

Ultraviolet Stabilizer

Any chemical compound that, when admixed with a resin, selectively absorbs ultraviolet rays.

Ultraviolet/Visible Absorption Spectroscopy

An analytical technique that measures the wavelength-dependent attenuation of ultraviolet, visible, and near-infrared light by an atomic or molecular species; used in the detection, identification, and quantification of numerous atomic and molecular species.

Unary System

Composed of one component.

Unbond

An area within an adhesively bonded interface between two adherends in which the intended bonding action failed to take place, or an area in which two layers of prepreg in a cured component do not adhere. Also used to denote specific areas deliberately prevented from bonding in order to simulate a defective bond, such as in the generation of quality standard specimens.

Uncertainty

(1) An indication of the variability associated with a measured value that takes into account two major components of error: (a) *bias* and (b) the random error attributed to the imprecision of the measurement process. (2) The range of values within which the true value is estimated to lie. It is a best estimate of possible inaccuracy due to both random and systematic errors.

Unctuous

A general term expressing the slippery feel of a material, such as a lubricant, when rubbed with the fingers.

Underannealing

Generally, in a pejorative sense, annealing at a temperature or for a time insufficient to induce full softening. The term is also used in a more specific sense when referring to the deliberate annealing of steel in the transition range so that the pearlite areas and a proportion of the ferrite areas are recrystallized.

Underbead Crack

A crack in the heat-affected zone of a weld generally not extending to the surface of the base metal. See also the term *weld crack*.

Undercoat

A deposited coat of material that acts as a substrate for a subsequent thermal spray deposit. See also *bond coat*.

Undercooling

Same as *supercooling*.

Undercure

An undesirable condition of a molded plastic article resulting from the allowance of too little time and/or temperature or pressure for adequate hardening of the molding.

Undercut

(1) In weldments, a groove melted into the base metal adjacent to the toe or root of a weld and left unfilled by weld metal. (2) For castings or forgings, same as *back draft*. (3) A reentrant detail on a casting. (4) A localized reduction in some machined dimension, intentional or otherwise. If unintentional, the term may be used in the sense of a stress raiser.

Underdraft

A condition wherein a metal curves downward or leaving a set of rolls because of higher speed in the upper roll.

Underfill

(1) In weldments, a depression on the face of the weld or root surface extending below the surface of the adjacent base metal. (2) A portion of a forging that has insufficient metal to give it the true shape of the impression.

Underfilm Corrosion

Corrosion that occurs under organic films in the form of randomly distributed threadlike filaments or spots. In many cases, this is identical to *filiform corrosion*.

Underflushing (of Weld)

See *flushing*.

Undersize Powder

Powder particles smaller than the minimum permitted by a particle size specification.

Understressing

(1) Applying a cyclic stress lower than the *endurance limit*. This may improve fatigue life if the member is later cyclically stressed at levels above the endurance limit. (2) In fatigue, the deliberate application of one or more cycles at a stress below, but usually close to the *fatigue limit*. This can have a strain aging effect improving the fatigue properties half-life.

UNE, UNO, UNQ, etc.

It has been proposed that man-made elements, particularly those discovered in the future, be named in terms of their atomic number in pseudo-Latin. Hence, element 104 is un-nil-quadam, that is, “unnilquadam” shortened to UNQ, etc.

Uniaxial

Acting or aligned along one axis of a crystal or a component.

Uniaxial Compacting

Compacting of powder along one axis, either in one direction or in two opposing directions. Contrast with *isostatic pressing*.

Uniaxial Load

A condition in which a material or component is stressed in only one direction along its axis or center line.

Uniaxial Strain

See *axial strain*.

Uniaxial Stress

A state of stress in which two of the three principal stresses are zero. See also *principal stress (normal)*.

Unidirectional Compacting

Compacting of powder in one direction.

Unidirectional Laminate

A reinforced plastic laminate in which substantially all of the fibers are oriented in the same direction. See the terms *laminate* and *quasi-isotropic laminate*.

Uniform Corrosion

(1) A type of corrosion attack (deterioration) uniformly distributed over a metal surface. (2) Corrosion that proceeds at approximately the same rate over a metal surface. Also called general corrosion.

Uniform Elongation

The elongation at maximum load and immediately preceding the onset of necking in a tensile test.

Uniformly Distributed Impact Test

See *distributed impact test*.

Uniform Magnetic Heating

Uniform magnetic heating (UMH) is a system by which electrical energy is converted to heat within metallic materials in a very efficient and flexible manner. Although this system and conventional

induction heating both require electrical coils to convert electricity to magnetic flux energy, the similarities stop there.

UMH versus Induction

The CoreFlux UMH system utilizes two coils that are permanently fixed around a C-shaped laminate core. Similar to induction systems, the coils convert electrical energy into magnetic flux energy. However, in conventional induction, the component to be heat treated is placed inside the coil. The energy is directly transferred to the part in the form of surface eddy currents, which are generated as the current flows around the component.

The CoreFlux system transfers energy in a different way. Energy is transferred into a laminate core (similar to a transformer core) and channeled directly to the part in a linear manner. In this way, the magnetic flux energy is distributed throughout the entire part. Key to the technology is that the flux direction in the core oscillates at a user-defined frequency from 20 to 400 Hz. As a result, the polarity of the flux field changes at this defined frequency. Each time the polarity changes, heat is released throughout the component via “hysteresis loss.”

Simply put, hysteresis loss is the energy released throughout the material as the magnetic domains in the microstructure are forced to realign continually with the alternating magnetic field. The effect of this phenomenon is the uniform production of heat throughout the component.

Because of the inherent nature of this method, the core and surface temperatures show minimal thermal gradients throughout the entire heating process. With induction, localized overheating of components with holes and unusual characteristics is a common problem, but overheating is not typically a concern with UMH.

In addition to the benefits of uniform through-heating, UMH also provides several other key advantages:

- The coils are permanently fixed to the machine and require no maintenance or coil changeovers.
- The same coils can run a wide range of processes and bring the benefit of flexibility by running families of parts with no coil changes required.
- Metallurgical results are typically significantly better than conventional systems.
- The machine requires no water cooling, which results in lower facility costs, less maintenance, and no energy loss through heated water.
- Energy efficiency can be as much as twice that of conventional induction. The power supply is basically a standard ac variable motor drive. This eliminates costly custom power supplies and the problems associated with their maintenance. It also greatly reduces overall capital equipment costs.

Applications**Heating Press Dies**

One simple application of the technology that offers significant benefits is the heating of press dies. A variety of die shapes may be placed in a common machine that can heat the dies to the required temperature in a matter of minutes. As an alternative to oven preheating, the UMH process offers much faster, cleaner, and more efficient heating and allows customers to change dies more quickly. Machines may also be mobile so that one machine can serve multiple press locations. Current size and shape capabilities range from

U

very small to approximately $180 \times 45 \times 45$ cm. Larger components may be accommodated with custom designs.

Tempering Gears and Bearings

One of the most promising areas of publication for this technology is the tempering of gears and bearings. Parts do not need to be rotated, and taller parts do not require scanning. For example, if a component has a round shape and an inner bore, the CoreFlux UMH technology can be applied by utilizing a core extension. The component is placed around the core extension, which provides a secondary field but causes very rapid and uniform heating with no part contact. UMH generates a uniform field throughout the component, from the inner core extension. On the other hand, if the part were induction tempered, the coil would be placed around the outside diameter, and the field would be generated from the outside inward to the core.

Fortunately, the CoreFlux UMH process overcomes time at temperature and the skin effect phenomenon. Because of the uniformity of heating, the core of the gear comes to temperature at virtually the same rate as the teeth. Metallurgical results typically exceed expectations and return properties similar, and sometimes superior, to oven tempering. An additional benefit is the ability to run multiple parts around the same core extension. Depending on the actual geometry, parts can be stacked around the core extension with minimal effect on the total cycle time. Obviously, this can have a profound effect on production throughput and machine utilization.

Hardening Gears and Bearings

The same core extension approach described earlier may be utilized for high-temperature applications. Although the research and documentation related to hardening are less mature than the lower-temperature applications, the technology has again demonstrated substantial benefits over today's alternatives. Targeted as hardening applications only, the technology offers the same flexibility as tempering. In fact, UMH has potential for the design of an entire hardening and temporary line that could allow for the flexible running of components inside a large "family" grouping, with those setup changes.

Heating Aluminum Billets

The properties of aluminum make difficult to through-heat quickly and uniformly by conventional technology. With the CoreFlux UMH process, and aluminum billet may be placed directly on the insulated core cap, and the top core/coil assembly may then be lowered to make light contact with the billet. This clamping effect is utilized to create the most efficient transfer of energy into the billet and to facilitate holding the billet in place during heating. Clamping pressure is adjustable to eliminate any marking or deformation.

Capabilities have been documented and proven, and application development continues in the aluminum field, with preheating applications ranging from 370°C to semisolid temperatures. Although steel forging offers similar promise, development continues in this area to assure that the machine cores will endure long exposures to extreme forging temperatures.

Shrink-Fit Applications

Another simple through-heat application is preheating components for shrink fitting. Again, when compared with any other alternatives available for lower-temperature through-heating, the CoreFlux UMH process is an improvement.

Press Tempering

Although a relatively new development, press-temper applications have drawn considerable attention. In cases where thin parts must

be stacked and held flat during tempering or stress relieving, the CoreFlux process is worth considering. The top coil and core assembly are typically lowered via pneumatic cylinders, and the clamping pressure is limited to as little as a pound. However, the pressure can be adjusted to provide more than a ton of damping force if necessary. If higher force is required, the machine can be customized. In addition, this system could allow for the pressure to be controlled as a function of temperature.

Uniform Strain

The strain occurring prior to the beginning of localization of strain (necking); the strain to maximum load in the tension test.

Unimeric

Pertaining to a single molecule that is not monomeric, oligomeric, or polymeric, such as saturated hydrocarbons.

Unipolarity Operation

A resistance welding process variation in which succeeding welds are made with pulses of the same polarity.

Unit Cell

A parallelepiped element of crystal structure, containing a certain number of atoms, the repetition of which through space will build up the complete crystal. See the term *lattice*.

Unit Power

The net amount of power required during machining or grinding to remove a unit volume of material in unit time.

Univariant Equilibrium

A stable state among several phases equal to one more than the number of components, that is, having one degree of freedom.

Universal Forging Mill

A combination of four hydraulic presses arranged in one plane equipped with the billet manipulators and automatic controls, used for radial or draw forging. See the term *radial forging*.

Universal Gas Constant

See *gas constant*.

Universal Mill

A rolling mill in which rolls with a vertical axis roll the edges of the metal stock between some of the passes through the horizontal rolls that are capable of working through all surfaces of the section.

Unlubricated Sliding

Sliding without lubricant but not necessarily under completely dry conditions. Unlubricated sliding is often used to mean "not intentionally lubricated," but surface species such as naturally formed

surface oxides and other interfacial contaminants may act in a *lubricant manner* is nominally unlubricated sliding.

Unsaturated Compounds

Any chemical compound having more than one bond between two adjacent atoms, usually carbon atoms, and being capable of adding other atoms at that point to reduce it to a single bond, for example, *olefins*.

Unsaturated Polyester Resin

The use of unsaturated polyester resins in structural applications is well documented. There are, however, significant quantities of unsaturated polyester resins used in specialist compounded products, which are more likely to be unreinforced. The most well known of these technologies are formulated gel coats, a technology that has been changing rapidly in recent years with improvements in gloss retention, color retention, and volatile organic compound emissions.

The introduction of granite effect coatings and solid surface material is a further example of the versatility of unsaturated polyester resins. Although these materials have been predominantly used for interior applications, their potential for exterior use on buildings provides exciting possibilities for a new and varied range of composite building materials providing stone effects at a fraction of the weight of conventional building materials.

Other compounded resins that are especially important to the building and construction market are those with fire-resistant characteristics. In addition, the improvements in smoke reduction from unsaturated polyester resin systems make such materials attractive for cladding applications. Combining the advantages of these resins with decorative coatings and sandwich construction provides the basis for structural, insulating components.

Markets

The markets for reinforced plastics are frequently split into a number of generally accepted sectors, such as marine, land transport, building and construction, and chemical containment. There are, of course, subdivisions in each sector, for example, powered pleasure boats, powered work boats, sailboats, and offshore applications in the marine market, but most of the discussion in the literature is about the use of fiber-reinforced composites in these market sectors and market subgroups. In general, unfilled resins with good mechanical properties are preferred, but there are, very often, requirements for compounded products to provide special characteristics to meet specific performance requirements. Obviously, compounded fire-resistant materials fall into such a category and are used to impart resistance to ignition, resistance to surface spread of flame, and, increasingly, reduction in emissions of smoke and toxic fumes. Although such materials are often highly filled, they are used with fiber reinforcement for the manufacture of structural and semistructural components. The importance of these resins and their developments together with two other important compounded unsaturated polyester resin-based products has been disclosed. These latter materials are not used in conjunction with fiber reinforcement but are usually simply filled or pigmented; they are gel coats and are mainly used as “in-mold” coatings and solid surface materials for the manufacture of synthetic granite-type products.

Resin concrete and repair putties are also large consumers of unsaturated polyester resin in non-fiber-reinforced compounds.

Resistance to Fire

The use of glass-fiber-reinforced plastics in applications where fire resistance was particularly important was introduced into the building industry five decades ago. Generally, the structural performance of the material was not questioned for building applications because it had been well proven for the construction of boats. However, as with most plastic materials, its ability to perform under fire conditions was in question for use in buildings, even though it had been documented that fires in buildings originate from the contents and in a vast majority of circumstances the structure does not contribute to loss of life.

One of the most successful means to improve the resistance of plastics to fire is by the incorporation of fillers, which break down with heat to produce heavy vapors to prevent oxygen reaching the surface of the material and hence reduce the possibility of burning. The major problem associated with the high levels of filler required to render resins fire retardant is the increase in their viscosity, which results in handling difficulties when manufacturing structural components.

The use of halogenated additives, which work synergistically with some fire-retardant fillers, helps to overcome handling problems but results in the potential for toxic fume production under fire conditions.

The availability of improved viscosity modifiers is now enabling resins filled with high levels of nontoxic fillers, such as alumina trihydrate, to be used to manufacture laminates containing reasonable levels of reinforcement to produce, at least, semistructural components.

Such systems will meet the new International Maritime Organization requirements for use on passenger ships. Under the test conditions, the material has to exhibit low surface spread of flame characteristics, low smoke emissions, and low emissions of carbon monoxide.

Gel Coat Protection

In the early days of the GRP industry, the need for resin-rich surfaces was established to

- Improve the durability of components
- Protect the laminate from the environment
- Reduce fiber pattern
- Provide a smooth aesthetic finish
- Eliminate the need for painting

As a result of these requirements, a market for ready-formulated coatings was established and gel coat product ranges became established.

The availability of quality “in-mold” coatings, such as gel coats, to fabricators saves labor and wastage in the workshop and improves the quality of molded components. Gel coats are available in brush and spray versions with a variety of properties and performance characteristics to meet a range of needs. They must be applied carefully and correctly to avoid faults.

Gel Coat Developments

Over the years, the need for improved gloss and color retention in gel coats has been recognized as developments in ultraviolet resistance and color fastness have resulted in a range of gel coats that can be weathered under the severest tropical weather conditions without changes in appearance.

Solid Surfaces

Resins have often been used to bind together fillers and aggregates to produce materials such as resin concrete and synthetic cultured

U

and onyx marble. For decorative surfaces, a clear (translucent) gel coat is used to improve the quality of the surface finish and remove the effects of surface porosity. Although the gel coat used is usually based on good-quality, water-resistant resins, the inferior quality of the backing systems often results in a material that is susceptible to crazing, cracking, poor water resistance, and poor thermal resistance. Because the gel coat surface is too thin for repairs to be effectively carried out, the problems cannot be easily rectified.

The monopoly of the acrylic-based solid surface material has been gradually eroded by the introduction of unsaturated polyester-based solid surface, which offers a much wider range of colors to provide improved customer choice. Raw materials and manufacturing processes have been designed to eliminate voids in polyester-based solid surfaces.

Traditionally, solid surface materials have been used for the manufacture of kitchen surfaces, sinks, and bathroom units. However, there is increasing interest in more diverse applications such as furniture, table tops, tiles, paneling, cutlery, and pens. It is also possible to use the material as a 2–3 mm thick coating for other materials, and the granite effect finish is reviving interest in GRP for cladding for buildings.

The unsaturated polyester resin-based material is comprised of three components:

1. *Chips*: The colored fillers or chips, used to provide the granite effect, can be based on thermoplastic or thermoset materials.
2. *Resins*: Resin must be clear and near “water white” to allow the depth of color of the chips to be appreciated. The resin must also be resistant to elevated temperature, water, staining, UV light, and cigarette burns. Hence, typical formulations giving an acceptable level of performance are based on isophthalic acid and neopentyl glycol.
3. *Fillers*: Only alumina trihydrate can be used in addition to the colored “chips” because it is translucent. It also offers fire-retardant characteristics.

Solid surface systems are nonreinforced that can be machined and cut with conventional woodworking equipment. Patterns can be routed in solid surface materials and cast resin “inlaid” to provide a variety of customized finishes.

It is important to ensure when manufacturing solid surface that the resin is formulated to accept high filler loading without air entrapment and will develop hardness rapidly. The final product must be resistant to chipping, cracking, hot–cold water cycling, “blushing,” and UV light. It must also be easy to machine for shaping and finishing.

Future

Unsaturated polyester resin-based compounded products provide a range of materials with tailored performance characteristics for a variety of markets.

Gel coats are essential for most applications for GRP, providing aesthetic finishes in the marine, transport, building, and construction markets. They have well-proven durability, but improvements in gloss and color retention will ensure their position as a major coating for fiber-reinforced composite materials in the future.

Fire-retardant resins with exceptionally low smoke production under fire conditions are becoming a reality with unsaturated polyester resin-based systems. New standards are providing new challenges, which are being met successfully to ensure that materials meet new requirements for surface spread of flame for materials for use in construction applications.

Unsoundness

This term usually implies volumetric defects such as internal cavities, voids, and porosity as opposed to planar defects such as crack or upper yield. See *tensile test*.

Unsymmetric Laminate

A *laminate* having an arbitrary stacking sequence without midplane symmetry.

Upper Punch

The member of a die assembly or tool set for forming powder metallurgy parts that closes the die and forms the top of the part being produced.

Upper Ram

The part of a pneumatic or hydraulic press for forming powder metallurgy parts that is moving in an upper cylinder and transmits pressure to the upper punch or set of upper punches.

Upset

(1) The localized increase in cross-sectional area of a workpiece or weldment resulting from the application of pressure during mechanical fabrication or welding. (2) That portion of the welding cycle during which the cross-sectional area is increased by the application of pressure. (3) Bulk deformation resulting from the application of pressure in welding. The upset may be measured as a percent increase in interfacial area, a reduction in length, or a percent reduction in thickness (for lap joints). (4) A local increase in cross-sectional area resulting from a longitudinal force. The term is commonly used in operations where the deformation is delivered in a die that is used to shape the upset, for example, the formation of a bolt head. The process is beneficial as it produces a desirable flow, that is, pattern of deformation, and it reduces the amount of machining.

Upset Butt Welding

Same as *resistance butt welding*.

Upset Forging

A forging obtained by *upset* of a suitable length of bar, billet, or bloom.

Upset Pressing

The pressing of a powder compact in several stages, which results in an increase in the cross-sectional area of the part prior to its ejection.

Upsetter

A horizontal mechanical press used to make parts from bar stock or tubing by *upset forging*, piercing, bending, or otherwise forming in dies. Also known as a *header*.

Upsetting Force

In *upset welding*, the force exerted at the faying surfaces during upsetting. See also *upset* (3).

Upsetting Time

In *upset welding*, the time during upsetting. See also *upset* (3).

Upset Weld

A weld made by *upset welding*.

Upset Welding

A resistance welding process in which the weld is produced, simultaneously over the entire area of abutting surfaces or progressively along a joint, by applying mechanical force (pressure) to the joint and then causing electrical current to flow across the joint to heat the abutting surfaces. Pressure is maintained throughout the heating period. See also *open-gap upset welding*.

Upslope Time

In resistance welding, the time during which the welding current continuously increases from the beginning of welding current. See also *slope control*.

Uranium

An elementary metal (symbol U), uranium never occurs free in nature but is found chiefly as an oxide in the minerals pitchblende and carnotite where it is associated with radium. The metal has a specific gravity of 18.68 and atomic weight 238.2. The melting point is about 1133°C. It is hard but malleable, resembling nickel in color, but related to chromium, tungsten, and molybdenum. It is soluble in mineral acids.

Uranium has three forms. The alpha phase, or orthorhombic crystal, is stable at 660°C; the beta, or tetragonal, exists from 660°C to 760°C; and the gamma, or body-centered cubic, is from 760°C to the melting point. The cast metal has a hardness of 80–100 Rockwell B, making work-hardening easy. The metal is alloyed with iron to make ferrouanium, used to impart special properties to steel. It increases the elastic limit and the tensile strength of steels and is also a more powerful deoxidizer than vanadium. It will denitrogenize steel and has also carbide-forming qualities. It has been used in high-speed steels with 0.05%–5% to increase the strength and toughness, but because of its importance for atomic applications, its use in steel is now limited to the by-product nonradioactive isotope uranium-238.

Uses

Metallic uranium is used as a cathode in photoelectric tubes responsive to ultraviolet radiation. Uranium compounds, especially the uranium oxides, were used for making glazes in the ceramic industry and also for paint pigments. It produces a yellowish-green fluorescent glass, and a beautiful red with yellowish tinge is produced on pottery glazes. Uranium dioxide, UO_2 , is used in sintered forms as fuel for power reactors. It is chemically stable and has a high melting point at about 2760°C, but a low thermal conductivity. For fuel use, the particles may be coated with about 0.003 cm of aluminum oxide. The coating is impervious to xenon and other radioactive isotopes so that only the useful power-providing rays can escape. These are not dangerous at a distance of about 15 cm, and thus less shielding is needed. For temperatures above 1260°C, a coating of pyrolytic graphite is used.

Uranium has isotopes from 234 to 239, and uranium-235, with 92 protons and 143 neutrons, is the one valued for atomic work.

Natural uranium does not normally undergo fission because of the high probability of the neutron being captured by the U^{238} that then merely ejects a gamma ray and becomes U^{239} . When natural uranium is not in concentrated form, but is embodied in a matrix of graphite or heavy water, it will sustain a slow chain reaction sufficient to produce heat. In the fission of U^{235} , neutrons are created that maintain the chain reaction and convert U^{238} to plutonium. About 40 elements of the central portion of the periodic table are also produced by the fission, and eventually these products build up to a point where the reaction is no longer self-sustaining. The slow, non-explosive disintegration of plutonium yields neptunium. *Uranium 233* is made by neutron bombardment of thorium. This isotope is fissionable and is used in thermonuclear reactors.

Uranium yellow, also called *yellow oxide*, is a *sodium diuranate*, obtained by reduction and treatment of the mineral pitchblende. It is used for yellow and greenish glazing enamels and for impacting an opalescent yellow to glass, which is green in reflected light. *Uranium oxide* is an olive-green powder of composition U_3O_8 , used as a pigment. *Uranium trioxide*, UO_3 , is an orange-yellow powder also used for ceramics and pigments. It is also called *uranic oxide*. As a pigment class, it produces a beautiful greenish-yellow *uranium glass*. *Uranium pentoxide*, U_2O_5 , is a black powder, and *uranous oxide*, UO_2 , is used in glass to give a fine black color. The uranium oxide colors give luster and iridescence, but because of the application of the metal-to-atom work, the uses in pigments and ceramics are now limited.

Uranium Ores

The chief source of radium and uranium is *uraninite*, or *pitchblende*, a black, massive, or granular mineral with pitch-like luster. The mineral is a combination of the oxides of uranium together with small amounts of lead, thorium, yttrium, cerium, helium, argon, and radium. The process of separation of radium is chemically complicated. Numerous minor uranium ores occur in many areas. A low-grade ore of 0.1% uranium oxide can be upgraded to as high as 5% by ion exchange.

Uranyl

The chemical name designating the UO_2^{2+} group and compounds containing this group.

Urea

Also called *carbamide*, urea is a colorless to white crystalline powder best known for its use in plastics and fertilizers. The chemistry of urea and the carbamates is very complex, and a great variety of related products are produced. Urea is produced by combining ammonia and carbon dioxide, or from cyanamide. It is a normal waste product of animal protein metabolism and is the chief nitrogen constituent of urine. It was the first organic chemical ever synthesized commercially. It has a specific gravity of 1.323, with a melting point of 135°C.

Types

The formula for urea may be considered to be $\text{O} \cdot \text{C}(\text{NH}_2)_2$ and thus an amide substitution in carbonic acid, $\text{O} \cdot \text{C}(\text{OH})_2$, an acid that really exists only in its compounds. The urea-type plastics are called amino resins. The carbamates can also be considered as deriving

U

from carbamic acid, NH_2COOH , an aminoformic acid that likewise appears only in its compounds. The carbamates have the same structural formula as the bicarbamates so that sodium carbamate has an NH_2 group substituted for each OH group of the sodium bicarbonate. The urethanes used for plastics and rubber are alkyl carbamates made by reacting urea with an alcohol or by reacting isocyanates with alcohols or carboxyl compounds. They are white powders melting at 50°C .

Isocyanates are esters of isocyanic acid, which does not appear independently. That dibasic diisocyanate is made from a 36-carbon fatty acid. It reacts with compounds containing active hydrogen. With modified polyamines, it forms polyurea resins, and with other diisocyanates, it forms a wide range of urethanes. Tosyl isocyanate producing urethane resins without a catalyst is toluene sulfonyl isocyanate. The sulfonyl group increases the reactivity.

Methyl isocyanate is a colorless liquid with a specific gravity of 0.9599. It reacts with water. With a flashpoint of less than -6.6°C , it is flammable and creates risks for fire. It is a strong irritant and is highly toxic. One of its principal uses is as an intermediate in the production of pesticides.

Urea is used with acid phosphates in fertilizers. It contains about 45% nitrogen and is one of the most efficient sources of nitrogen. Urea reacted with malonic esters produces malonyl urea, which is the barbituric acid that forms the basis for the many soporific compounds such as *luminal*, *phenobarbital*, and *amytal*. The malonic esters are made from acetic acid, and malonic acid derived from the esters is a solid that decomposes at about 160°C to yield acetic acid and carbon dioxide.

For plastics manufacture, substitution on the sulfur atom in thiourea is easier than on the oxygen in urea. Thiourea, also called *thiocarbamide*, *sulfourea*, and *sulfocarbamide*, is a white, crystalline, water-soluble material of bitter taste, with a specific gravity of 1.405. It is used for making plastics and chemicals. On prolonged heating below its melting point, 182°C , it changes to ammonium thiocyanate, or ammonium sulfocyanide, a white, crystalline, water-soluble powder melting at 150°C . This material is also used in making plastics; used as a mordant in dyeing, to produce black nickel coatings; and used as a weed killer. *Permafresh*, used to control shrinkage and gives wash-and-wear properties to fabrics, is dimethylol urea, which gives clear solutions to warm water.

Urea-formaldehyde resins are made by condensing urea or thiourea with formaldehyde. They belong to the group known as amino-aldehyde resins made by the interaction of an amine and an aldehyde. An initial condensation product is obtained that is soluble in water and is used in coatings and adhesives. The final condensation product is insoluble in water and is highly chemical resistant. Molding is done with heat and pressure. The urea resins are noted for their transparency and ability to take translucent colors. Molded parts with cellulose filler have a specific gravity of about 1.50, tensile strength 41–89 MPa, elongation 15%, compressive strength 310 MPa, dielectric strength 16×10^6 V/m, and a heat distortion temperature of 138°C . Rockwell hardness is about M 118. Urea resins are marketed under a wide variety of trade names: the *Uformite* resins, which are water-soluble thermosetting resins for adhesives and sizing; the *Urac* resins; and the *Casco* resins and *Cascomite*, or urea-formaldehyde. They are used for plasterboard, plywood, and in wet-strength paper.

Urea-Formaldehyde Adhesive

(1) An aqueous colloidal dispersion of urea-formaldehyde polymer that may contain modifiers and secondary binders to provide

specific adhesive properties. (2) A type of adhesive based on a dry urea-formaldehyde polymer and water. A curing agent is commonly used with this type of adhesive.

Urethane Hybrids

Urethane acrylic polymers that are formed by the reaction of two liquid components, an acrylesterol and a modified diphenylmethane-4,4'-diisocyanate (MDI). The acrylesterol is a hybrid of a urethane (monoalcohol) and an acrylic (unsaturated monoalcohol). The liquid-modified MDI contains two or more isocyanate groups that can react with the hydroxyl portion of the acrylesterol molecule. Acrylamate resin systems are reinforced with glass (30%–40%) and are used in automotive applications and recreational products. When reinforced with carbon mat or metallized glass cloth, these materials can be used in communication equipment, such as electromagnetic interference/radio-frequency interference devices.

Urethanes

Also termed polyurethanes, urethanes are a group of plastic materials based on polyether or polyester resin. The chemistry involved is the reaction of a diisocyanate with a hydroxyl-terminated polyester or polyether to form a higher-molecular-weight prepolymer, which in turn is chain extended by adding difunctional compounds containing active hydrogens, such as water, glycols, diamines, or amino alcohols. The urethanes are block polymers capable of being formed by a literally indeterminate number of combinations of these compounds. The urethanes have excellent tensile strength and elongation, good ozone resistance, and good abrasion resistance. Combinations of hardness and elasticity unobtainable with other systems are possible in urethanes, ranging from Shore hardnesses of 15–30 on the “A” scale (printing rolls, potting compounds) through the 60–90 A scale for most industrial or mechanical goods applications to the 70–85 Shore “D” scale. Urethanes are fairly resistant to many chemicals such as aliphatic solvents, alcohols, ether, certain fuels, and oils. They are attacked by hot water, polar solvents, and concentrated acids and bases.

Urethane Foams

Urethane foams are made by adding a compound that produces carbon dioxide or by reaction of a diisocyanate with a compound containing active hydrogen. Foams can be classified somewhat according to modulus as flexible, semiflexible or semirigid, and rigid. No sharp lines of demarcation have been set on these different classes as the gradation from the flexibles to the rigids is continuous. Densities of flexible foams range from about 16 kg/m^3 at the lightest to $64\text{--}80 \text{ kg/m}^3$ depending on the end use. Applications of flexible foams range from comfort cushioning of all types, for example, mattresses, pillows, sofa seats, backs, and arms, automobile topper pads, rug underlay, and clothing interliners for warmth at light weight.

Flexible Types

The techniques of manufacture of flexible urethane foam vary widely, from intermittent hand mixing to continuous machine operation, from prepolymer to one-shot techniques, from slab forming to molding, and from stuffing to foamed-in-place.

Future applications envision the flexible foam not as a substitute for latex rubber foam or cotton but as a new material of construction allowing for design of furniture, for example, which is essentially all foam with a simple cloth cover and a very simple metal-supporting framework.

Rigid Types

Densities from about 24 to 800 kg/m³ on the semirigid side have been produced with corresponding compression strengths again for particular end uses ranging from installation to fully supporting structural members. The usefulness of the urethane system has been in the foamed-in-place principle using a host of containing wall materials.

Applications to the more rigid foam field have been thermal insulation of all types (low-temperature refrigeration ranging from liquid nitrogen temperatures to the freezing point of water and high temperature insulation of steam pipes, oil lines, etc.); shock absorption such as packaging and crash pads, where the higher hysteresis values produce either a better one-time high-impact "crash" use or, more often, lower-amplitude but higher-frequency container end use; filtration (air, oil, etc., where a large surface-to-volume ratio is needed with a simple technique to produce a reusable filter to allow for its additionally higher cost factor); structural (building applications of all kinds, combining a good thermal as well as structural behavior, and filling of building voids; curtain walls are some basic applications); flotation (boats, buoys, and every other imaginable objects afloat represent some possible application of urethane foams); and general-purpose applications that include all other uses such as decorative applications.

Rigid foams can be produced using a simple spray technique, and a number of machines are sold on the market for this technique. Time-consuming layup of foam is eliminated using this method. Insulations of walls, tanks, etc., are applications in use today. With the use of low-vapor-pressure isocyanates such as 4,4'-diphenylmethane diisocyanate, the potential irritant hazard during spraying is greatly lowered. Self-adhesion of the sprayed foam is a valuable asset of this type of system.

Urethane foams offer advantages over many of the better-known foams such as latex foam rubber, polystyrene, and polyethylene, with the combination of excellent properties and lower installed costs. Depending on the application, a lower foam density can be used with similar load-bearing properties, also one having an extremely low thermal conductivity be fabricated. The oil resistance, high-temperature resistance, good high-tensile properties, good permanence properties, resistance to mildew, resistance to flammability, and so on are in general the types of properties that, combined with foamed-in-place technology, put urethane foam far ahead of competitive materials.

Other Urethanes

Thermoplastic polyurethanes (TPUs) include two basic types: esters and ethers. There are also TPUs based on polycaprolactone, which, while technically being esters, have better resistance to hydrolysis. TPUs are used when a combination of toughness, flex resistance, weatherability, and low-temperature properties is needed. These materials can be injection molded, blow molded, and extruded as profiles, sheet, and film. Further, TPUs are blended with other plastic resins, including polyvinyl chloride, ABS, acetyl, SAN, and polycarbonate.

Urethane elastomers are made with various isocyanates, the principal ones being tolylene diisocyanate and 4,4'-diphenylmethane diisocyanate, reacting with linear polyols of the polyester and polyether families. Various chain extenders, such as glycols, water, diamines, or aminoalcohols, are used in either a prepolymer or a one-shot type of system to form the long-chain polymer.

Flexible urethane fibers, used for flexible garments, are more durable than ordinary rubber fibers or filaments and are 30% lighter in weight. They are resistant to oils and to washing chemicals and

also have the advantage because of their white color. Spandex fibers are stretchable fibers produced from a fiber-forming substance at which a long chain of synthetic molecules are composed of a segmented polyurethane. Stretch before break of these fibers is from 520% to 610%, compared to 760% for rubber. Recovery is not as good as in rubber. Spandex is white and dyeable. Resistance to chemicals is good, but it is degraded by hypochlorides.

There are six basic types of polyurethane coatings, or urethane coatings, as defined by the American Society for Testing and Materials, Specification D16. Types 1, 2, 3, and 6 have long storage life and are formulated to cure by oxidation, by reaction with atmospheric moisture, or by heat. Types 4 and 5 are catalyst cured and are used as coatings or leather and rubber and as fast-curing industrial product finishes. Urethane coatings have good weathering characteristics as well as high resistance to stains, water, and abrasion.

Fabrication

Urethane elastomers can be further characterized by the method of fabrication of the final article. Three principal types of revocation are possible: (1) casting technique where a liquid prepolymer or a liquid mixture of all initial components (one-shot) is cast into the final mold, allowed to "set" and harden, and is then removed for final cure; (2) millable gum technique where conventional rubber methods and equipment are used to build the gum, add fillers, color, etc., and/or banbury, extrude, calender, and compression mold the final shaped item; (3) thermoplastic processing techniques where the resin can be calendered, extruded, and injection- or blow molded on conventional plastic machinery in final form (an important benefit here is that scrap can be reground and reused in fabricating other parts).

The choice of the proper method of fabrication largely depends on the economics of the process, because the properties of the final product may be about the same regardless of the method of fabrication. If a few large-volume items are needed, casting these into a single mold is usually more economical. However, if many thousands of small, intricate pieces are needed, usually injection molding is the preferred, more economical method of fabrication.

Uses

Applications of urethane elastomers have been developed where high abrasion resistance, good oil resistance, and good load-bearing capacity are of value, as in solid tires and wheels, especially of industrial trucks, the shoe industry, drive and belting applications, printing rolls, gasketing in oil, etc. Other applications include vibration dampening, for example, in hammer heads, air hammer handles, and shock absorption underlays for heavy machinery; low coefficient of friction with the addition of molybdenum disulfide for self-lubricating uses as ball-and-socket joints, thrust bearings, leaf spring slide blocks in the electrical industry, cable jacketing, and potting compounds are developing as important uses. Various systems of urethane elastomers with specific fillers have been developed into an important class of caulks and sealants, which are just beginning to take hold in applications such as concrete road-expansion joints and building caulking, in direct competition with such older materials as the polysulfides but at a much lower price and superior properties.

A host of other applications varies from adhesive bonding of fibers of all kinds to rocket fuel binders of the more exotic variety, which are becoming so important in the U.S. National Defense picture. Therefore, it is imperative that design engineers understand fully the material they are using and how they intend to utilize it in the final piece of equipment. For example, one recommendation is to limit the use of urethanes to below 82°C in water for continuous exposures.

U

Dry uses can go somewhat higher, for example, to 107°C for certain systems. In oil, exposures can be up to 121°C. Disregard of such limitations can result in failures, but the design engineer can eliminate these by the proper choice of material. On the other hand, the design engineer should choose the urethanes for their virtues, such as hardness and elasticity, where other materials such as natural and other synthetic rubbers may fail.

Properties

The urethanes have excellent tensile strengths and elongation, good ozone resistance, and good abrasion resistance. Knowledge of these properties is mandatory for good engineering design.

The greater load-bearing capacity of urethanes as compared to other elastomers is noteworthy, for it leads to smaller, less costly, lower-weight parts in equivalent applications. Tear strength is extremely high, which may be important in particular applications along with the very high tensile strengths. The high abrasion resistance has made possible driving parts for which no other materials could compete. However, in every such dynamic application, the engineer must design the part to allow for the higher hysteresis losses in the urethane. Whereas in some applications such as dampening the higher hysteresis works to advantage, in others hysteresis will lead to part failure if the upper temperature limit is thereby

exceeded. Redesign of the part (thinner walls) to allow for greater dissipation of the heat generated will permit the part to operate successfully. This has proved to be the case many times.

Urethane elastomers generally have good low-temperature properties. The same hysteresis effect works in reverse here so that a part in dynamic use at temperatures as low as -51°C, while stiff in static exposure, immediately generates enough heat in dynamic use to pass through its second-order transition and does not show any brittleness but becomes elastic and usable. By proper choice of the polyester or polyether molecular backbone, lower use temperatures (as low as -62°C) have been formulated in urethane elastomers.

In addition to good mechanical properties, urethanes have good electrical properties, which suggest a number of applications. Oxygen, ozone, and corona resistances of this system are generally excellent. See also *isocyanate plastics* and *polyurethanes*.

UTS

Ultimate tensile strength. See *tensile test*.

UV

See *ultraviolet*.

V

V

V Process

A molding (casting) process in which the sand is held in place in the mold by vacuum. The mold halves are covered with a thin sheet of plastic to retain the vacuum.

V Segregation

See *segregation*.

Vacancy

(1) A structural imperfection in which an individual atom site is temporarily unoccupied. (2) An unoccupied atomic site in a crystal lattice.

Vacancy Jump

The movement of atoms in substitutional solid solution into a vacant site. This can be regarded as a movement of the vacancy in the opposite direction.

Vacant Site

Same as *vacancy*.

Vacu-Blasting

A grit blasting process in which the grit or shot, after impacting the target component, is recovered by vacuuming for reuse.

Vacuum

A space that is devoid of matter. Loosely, a pressure less than atmospheric.

Vacuum Annealing

Annealing carried out at sub-atmospheric pressure.

Vacuum Arc Melting (VAM)

A purification process for metals such as steel and titanium and in which a DC electric arc is struck between an electrode of the impure metal and the water-cooled copper mold over which it is suspended. The impure electrode is progressively melted, and a new ingot solidifies in the mold. A high vacuum avoids oxidation and removes volatile elements. The process is deliberately slow with minimum turbulence allowing impurities to float to the surface of the molten metal.

Vacuum Arc Remelting (VAR)

A consumable-electrode remelting process in which heat is generated by an electrical arc between the electrode and the ingot. The process is performed inside a vacuum chamber. Exposure of the droplets of molten metal to the reduced pressure reduces the amount of dissolved gas in the middle. See the term *consumable-electrode remelting*.

Vacuum Atomization

A commercial batch powder production process based on the principle that, when a molten metal supersaturated with gas under pressure is suddenly exposed to vacuum, the gas expands, comes out of solution, and causes the liquid metal to be atomized. Alloy powders based on nickel, copper, cobalt, iron, and aluminum can be vacuum atomized with hydrogen. Powders are spherical, clean, and of a high purity.

Vacuum Bag

A flexible bag in which pressure may be applied to an assembly (inside the bag) by means of evacuation of the bag. See also *vacuum bag molding*.

Vacuum Bag Molding

A process for manufacturing reinforced plastics in which a sheet of flexible, transparent material plus a bleeder cloth and release film are placed over the lay-up on the mold and sealed at the edges. A vacuum is applied between the sheet and the lay-up. The entrapped air is mechanically worked out of the lay-up and removed by the vacuum, and the part is cured with temperature, pressure, and time. Also called *bag molding* or *pressure bag molding*. See also *lay-up*.

Vacuum Brazing

And nonpreferred term used to denote furnace brazing that takes place in a chamber or retort below atmospheric pressure.

Vacuum Carburizing

A high-temperature carburizing process using furnace pressures between 13 and 67 kPa (0.1–0.5 torr) during the carburizing portion of the cycle. Steels undergoing this treatment are austenitized in a rough vacuum, carburized in a partial pressure of hydrocarbon gas, diffused in a rough vacuum, and then quenched in either oil or gas. Both batch and continuous furnaces are used. See the term *vacuum furnace*.

Vacuum Carburizing

Heat treatment with gas quenching has already been an established heat treatment process for two or three decades in the field of

V

full hardening. At first, it was limited to the hardening of high-alloyed tool steels whose alloy structure enabled them to be hardened satisfactorily with a rather slow gas cooling rate.

The enhanced quenching action achieved with gas pressures above 10 bar has allowed successful extension of gas quenching to the field of low-alloyed tool steels, steels for hardening and tempering, antifriction-bearing steels, and case-hardening steels. The capability to carburize and gas-quench in vacuum furnace installations has provided the industry with a new, environmentally friendly case-hardening process.

The Process

Like plasma carburizing, vacuum carburizing can also be performed in a vacuum furnace system. Vacuum carburizing can be succinctly described by the following key points:

- Carburizing gas is propane.
- Pressure ranges up to 20 mbar (absolute).
- Temperature range is usually 900°C–1050°C, but higher temperatures are also possible.

Once the charge has been heated to the carburizing temperature under a neutral atmosphere (vacuum or nitrogen), propane is admitted into the evacuated heating chamber. Propane very rapidly undergoes 100% disassociation into more stable hydrocarbons and hydrogen. Carbon is also released and diffuses through the surface of the steel or component.

Vacuum carburizing is characterized by a high carbon mass flow rate, which carburizes the surface layer to near the carbon saturation limit within a short treatment time. In the subsequent diffusion phase, no more carburizing gas is fed in—rather, the existing carbon diffuses farther into the steel in accordance with the diffusion law until the desired carbon profile has been attained.

Process Comparisons

In contrast to protective-gas carburizing, vacuum carburizing can be performed with substantially higher case carbon contents. The case carbon percentage is already over 1.3% after a short period of carburization and then is held at 1.4%–1.5% at 930°C, which is about 0.2% higher than in protective-gas carburizing with a carbon level just below the sooting limit. The higher case carbon content in vacuum carburizing results in short treatment times, even at the same carburizing temperature. Raising the carburizing temperature results in a further considerable time savings.

Vacuum carburizing systems readily permit a carburizing temperature of over 1050°C, although the heat treatment racks made of heat-resistant cast steel (which are currently in use) are no longer usable at such high temperatures. With racks made of carbon-fiber-reinforced carbon (CFC), the limit is shifted to much higher temperatures. CFC material can only be used in an oxygen-free atmosphere such as that prevailing during vacuum carburizing. Of course, the carburizing action at the point of contact with the component must be taken into consideration.

The grain growth of case-hardening steels also does not permit such high temperatures over a long period of time. The vacuum furnace offers a pearlitizing treatment to refine the grain. Despite the time cost for pearlitizing, the result in comparison to the time required in a multipurpose protective-gas chamber furnace is a time savings of about 4 h for the case hardening of a 25%CrMo₄ steel to a case depth (550 HV) of 1.7 mm.

Distortion

Vacuum carburizing with gas quenching offers a potential for reduced parts distortion. A large number of experiments, conducted primarily on transmission parts, have shown that the scatter of the dimensional and shape changes after gas quenching is narrower than after oil quenching.

For example, a clutch body (O.D., 84 mm; I.D., 50 mm; height, 15 mm; mass, 0.2 kg each) made of 16%MnCr₅ with a case depth (550 HV) of 0.4–0.8 mm was tested. The study evaluated 50 clutch bodies after case hardening in the vacuum furnace (quenching with helium at 20 bar) and, for comparison, 50 others were evaluated after case hardening in the protective-gas furnace (oil quenching). The radial run-out of the clutch bodies was measured in the soft and hard states. The results are shown in *Ind. Heating*, January 54, 2000.

Advantages

Case hardening in vacuum heat treatment systems with gas quenching offers the user many advantages in comparison to conventional protective-gas carburizing with oil quenching. Parts are clean and dry after treatment requiring no washers or management or disposal of liquid waste. Leidenfrost phenomenon is avoided and with more uniform quenching, distortion is minimized. Vacuum carburizing also allows for carburizing at up to 1000°C.

As a protective atmosphere, vacuum can prevent case oxidation and eliminate toxic off-gases. Vacuum carburizing process also provides a high carbon mass flow rate with low consumption of carburizing gas. With regard to productivity, the vacuum process can be integrated into a production line without the burdening requirements for fire-protection and fire-extinguishing systems, excessive heat removal to the surroundings, or extensive exhaust gas handling.

In determining the carbon mass flow rate, it becomes clear that in the first few minutes of carburizing in this process (up to 30 min), there is a very high carbon mass flow rate of up to 100 g/m² h. The case-hardening steel can be carburized up to its limit of solubility in the surface layer without any sooting occurring. The system technology also makes it possible to carburize at temperatures above 1000°C. These two factors result in an enormously shortened process duration.

The carburization results are comparable with those of the protective-gas process with regard to case depth, case carbon content, and surface hardness. The advantages for component quality lie in reduced distortion. Investigations of various transmission parts have shown that the scatter of the dimensional and shape changes can be narrowed with gas quenching in comparison to oil quenching. The clean surface of the component and the absence of case oxidation after heat treatment are additional advantages of this technology.

Vacuum Casting

A casting process in which metal is melted and poured under very low atmospheric pressure; a form of permanent mold casting in which the mold is inserted into liquid metal, vacuum is applied, and metal is drawn out into the cavity.

Vacuum Coatings

The process of vacuum coating is used to modify a surface by evaporating a coating material under vacuum and condensing it on the surface. It is normally carried out under high-vacuum conditions (at approximately 1 millionth of an atmosphere pressure). The material

to be evaporated is heated until its vapor pressure appreciably exceeds the residual pressure within the vacuum system.

Vacuum coating can be used for many applications. For example, optical lenses are coated with magnesium fluoride to a fraction of a wavelength to prevent glare and provide much better transmission of light and a more reliable optical system. The deposited film is extremely adherent and will withstand normal cleaning.

Silicon monoxide is frequently used as an abrasion-resistant coating material. As deposited, it is soft and requires postheat treatment in air to convert it to silicon dioxide, which is transparent and extremely hard. It is frequently used to protect front surface mirrors and increases abrasion resistance by a factor of 5,000–10,000, while maintaining equal or higher reflectivity. Similarly, titanium is sometimes used for coating and is subsequently oxidized to yield a titanium dioxide abrasion-resistant surface.

By far the most common type of vacuum coating is the process of vacuum metallizing. In this process, metal is evaporated and used as deposited without further treatment as opposed to the evaporation of compounds or materials that require post-treatment.

Vacuum metallizing has generally been used as a decorative process whereby costume jewelry, toys, etc., are given a metallic sheen and are made highly reflective. The base material may be either plastic or metal. In either case, the part is frequently lacquered before metallizing to prevent the evolution of gas from the base and to provide a smooth surface without mechanical buffing. Because the metal deposit is only about 2 or 3 millionths of an inch thick, the smooth surface is necessary to give a specular reflection.

When the metal is on the outside of the coated part, it is referred to as front surface. However, in applications where it is used on the back of a transparent plastic (e.g., dashboards and taillight assemblies on automobiles), it is referred to as a second surface coating. The advantage of second surface coating is provided by using the plastic as the exposed surface. Front surface coatings must generally be protected with a transparent lacquer overcoat (applied after metallizing) because the thin decorative coatings are not wear resistant in themselves.

Aluminum is the most popular vacuum-metallizing coating material for most applications. However, other metals may be used, such as zinc, cadmium, copper, silver, gold, or chromium. Of all these metals, aluminum has the best general combination of reflectivity, conductivity, and stability in air. By adding color to the topcoat lacquer, the aluminum deposit may be made to appear like copper or gold as well as metallic sheens of blues, reds, yellow, etc. By using separate sources for each constituent, it is possible to deposit alloys as well as pure metals.

These applications are for parts produced by batch metallizing; that is, the individual parts are mounted on racks inserted in the vacuum system, and after the necessary vacuum and evaporation temperatures are obtained, the parts are rotated so that they are uniformly coated by the evaporating metal. In batch metallizing, the aluminum is evaporated from tungsten filaments, which are heated by direct resistance. Because of this, the amount of aluminum that can be charged is limited and only thin coatings can be produced. Similarly, only small surfaces (a few square centimeters), such as can be exposed within a matter of seconds, can be metallized.

When it is desirable to coat larger surfaces, for example, rolls of flexible material, a semi-continuous metallizing process must be employed. For semi-continuous metallizing, a roll of material is mounted in the vacuum chamber to coat either or both sides of the web, which is subsequently rewound in vacuum. This process is currently in use for coating rolls of plastic sheeting and paper. To coat continuously over a period of hours, it is necessary to have larger volumes of aluminum available for evaporation than can be held on

resistance-heated tungsten filaments. Therefore, the aluminum is generally heated by induction in crucibles.

Coating of rolls of materials provided one of the first functional applications for coatings that used the electrical conductivity of the metal deposited. This conductive layer was deposited on thin insulating layers of either paper or plastic and could be used for winding miniature condensers. The electrical conductivity is also used in the metallizing process itself as a means of measuring the amount of metal deposited. Since the conductivity is a function of the thickness of the metal, continuously measuring conductivity provides a control for the amount of metal deposited. Other functional uses of the coating are based on its reflectivity (e.g., reflective insulation).

Vacuum metallizing has recently been extended to include thick films, that is, in the range of 1–3 mils. Such coatings serve as corrosion-resistant barriers, particularly on high-tensile-strength steel exposed to marine atmospheres. Where the temperature requirements of steel are less than 260°C, cadmium deposits can be used. For temperatures in excess of this, aluminum shows much better protection and does not react with the base steel as cadmium does.

Truly continuous operation is necessary for coating rolled steel. Here, the rolls are unwound and rewound in air with the strip passing through seals into the vacuum chamber where it is coated. The metallizing of rolled stock allows separate control on each side of the web and the composition of the coating, as well as thickness, may be changed from one side to the other. There are several typical advantages of vacuum metallizing:

1. Close control of coating thickness and composition
2. Uniform deposits without buildup at sharp discontinuities
3. High coating rate
4. Low coating costs in volume production
5. Long life of equipment since few moving parts

There are also disadvantages of the process:

1. Part must be extremely clean.
2. Surfaces to be metallized must not evolve gas under vacuum.
3. Parts must not be temperature sensitive, that is, must be stable to about 125°C.
4. Deposits form well only on a surface exposed to hot metal; reentrant angles are not well coated.

The cost for metallizing in production lots for corrosion-resistant coatings is comparable to electroplating. Decorative metallizing is generally much less expensive than electroplating.

Vacuum Degassing

The use of vacuum techniques to remove dissolved gases from molten alloys.

Vacuum Deposition

Deposition of a metal film onto a substrate in a vacuum by metal evaporation techniques.

Vacuum Deposition (of Interference Films)

A method of revealing the microstructures of metals and carbides with the aid of vacuum-deposited interference layers (films). The phase shift in light reflected at the interference film/substrate

V

interface contributes to the colors produced by a transparent film on a metallographic specimen. This phase shift depends on the optical properties of the film and substrate. Materials that have been found to produce phase contrast and color when vacuum deposited include titanium dioxide (TiO_2), silicon dioxide (SiO_2), zirconium dioxide (ZrO_2), zinc sulfide (ZnS), tin oxide (SnO_2), and carbon. Of these, TiO_2 is the most commonly used. All these (except carbon) are supplied in powder or chips and must be contained in a tungsten wire basket, which is approximately 100 mm (4 in.) from the specimens. The vacuum chamber is evacuated to 10^{-4} torr or lower. See also *reactive sputtering* (of interference films).

Vacuum Forming

A method of sheet forming in which the plastic sheet is clamped in a stationary frame, heated, and drawn down by a vacuum into a mold. In a broad sense, the term is sometimes used to refer to all sheet-forming techniques, including *drape forming* involving the use of vacuum and stationary molds. See the terms *thermoforming* and *vacuum snapback thermoforming*.

Vacuum Furnace

(1) A furnace using low atmospheric pressures instead of a protective gas atmosphere like most heat-treating furnaces. Vacuum furnaces are categorized as hot wall or cold wall, depending on the location of the heating and insulating components. (2) Any furnace in which the charger is treated under vacuum. In melting furnaces, the vacuum extracts dissolved gases, as well as protecting from contamination. In heat treatment furnaces, it prevents oxidation, carburization, and contamination.

Vacuum Fusion

An analytic technique for determining the amount of gases in metals; ordinarily used for hydrogen and oxygen, and sometimes for nitrogen. Applicable to many metals, but not to alkali or alkaline earth metals.

Vacuum Hot Pressing

A method of processing materials (especially metal and ceramic powders) at elevated temperatures, consolidation pressures, and low atmospheric pressures.

Vacuum Induction Melting (VIM)

A process for remelting and refining metals in which the metal is melted inside a vacuum chamber by induction heating. The metal can be melted in a crucible and then poured into a mold.

Vacuum Injection Molding

A molding process for fabricating reinforced plastics that utilizes both a male and female mold in which reinforcements are placed, a vacuum is applied, and a room temperature curing liquid resin is introduced to saturate the reinforcement.

Vacuum Melting

Melting in a vacuum to prevent contamination from air and to remove gases already dissolved in the metal; the solidification can also be carried out in a vacuum or at low pressure.

Vacuum Metallizing

A process in which surfaces are simply coated by exposing them to a metal vapor under vacuum.

Vacuum Molding

See *V process*.

Vacuum Nitrocarburizing

A subatmospheric nitrocarburizing process using a basic atmosphere of 50% ammonia/50% methane, containing controlled oxygen additions of up to 2%.

Vacuum Plating

A form of vacuum deposition in which some reaction is involved such as between the surface and some vapor introduced into the vacuum chamber.

Vacuum Processing

Vacuum processing is used in many industrial applications. Some of these processes are shown as follows:

1. Annealing of metals
2. Degassing of metals
3. Electron beam melting
4. Electron beam welding
5. Evaporation
6. Sputtering of metals
7. Casting of resins and lacquers
8. Drying of plastics
9. Drying of insulating papers
10. Freeze-drying of bulk goods
11. Freeze-drying of pharmaceutical products

Through the use of vacuum, it is possible to create coatings with a high degree of uniform thickness ranging from several nanometers to more than 100 mm while still achieving very good reproducibility of the coating properties. Flat substrates, web and strip, as well as complex molded plastic parts, can be coated with virtually no restrictions as to the substrate material.

The variety of coating materials is also very large. In addition to metal and alloy coatings, layers may be produced from various chemical compounds or layers of different materials applied in sandwich form. A significant advantage of vacuum coating over other methods is that many special coating properties desired, such as structure, hardness, electrical conductivity, or refractive index, are obtained merely by selecting a specific coating method and the process parameters for a certain coating material.

Deposition of thin films is used to change the surface properties of a base material or substrate. For example, optical properties such as transmission or reflection of lenses and other glass products can be adjusted by applying suitable coating layer systems. Metal coatings on plastic web produce conductive coatings for film capacitors. Polymer layers on metals enhance the corrosion resistance of the substrate.

Coating Sources

In all vacuum coating methods, layers are formed by deposition of material from the gas phase. The coating material may be formed by

physical processes such as evaporation and sputtering, or by chemical reaction. Therefore, a distinction is made between physical vapor deposition (PVD) and chemical vapor deposition (CVD).

Thermal Evaporators

In the evaporation process, the material to be deposited is heated to a temperature high enough to reach a sufficiently high vapor pressure and the desired evaporation or condensation rate is set. The simplest sources used in evaporation consist of wire filaments, boats of sheet metal, or electrically conductive ceramics that are heated by passing an electrical current through them. However, there are restrictions regarding the type of material to be heated. In some cases, it is not possible to achieve the necessary evaporator temperatures without significantly evaporating the source holder and thus contaminating the coating. Furthermore, chemical reactions between the holder and the material to be evaporated can occur resulting in either a reduction in the lifetime of the evaporator or contamination of the coating.

Electron Beam Evaporators (Electron Guns)

To evaporate coating material using an electron beam gun, the material, which is kept in a water-cooled crucible, is bombarded by a focused electron beam and thereby heated. Since the crucible remains cold, in principle, contamination of the coating by crucible material is avoided and a high degree of coating purity is achieved. With a focused electron beam, very high temperatures of the material to be evaporated can be obtained and thus very high evaporation rates. Consequently, high-melting-point compounds such as oxides can be evaporated in addition to metals and alloys. By changing the power of the electron beam, the evaporation rate is easily and rapidly controlled.

Cathodic Sputtering

In the cathode sputtering process, the target, a solid, is bombarded with high-energy ions in a gas discharge. The impinging ions transfer their momentum to the atoms in the target material, knocking the atoms off. These displaced atoms—the sputtered particles—condense on the substrate facing the target. Compared to evaporated particles, sputtered particles have considerably higher kinetic energy. Therefore, the conditions for condensation and layer growth are very different in the two processes. Sputtered layers usually have higher adhesive strength and a denser coating structure than evaporated ones.

Sputter cathodes are available in many different geometric shapes and sizes as well as electrical circuit configurations. What all sputter cathodes have in common is a large particle source area compared to evaporators, and the capability to coat large substrates with a high degree of uniformity. In this type of process, metals and alloys of any composition, as well as oxides, can be used as coating materials.

Chemical Vapor Deposition

In contrast to physical vapor deposition methods, where the substance to be deposited is either solid or liquid, in chemical vapor deposition, the substance is already in the vapor phase when admitted to the vacuum system. To deposit it, the substance must be thermally excited, that is, by means of appropriate high temperatures or with plasma. Generally, in this type of process, a large number of chemical reactions take place, some of which are taken advantage of to control the desired composition and properties of the coating. For example, by using silicon–hydrogen monomers, soft silicon–hydrogen polymer coatings, hard silicon coatings, or—by the addition of oxygen—quartz coatings can be created by controlling process parameters.

Web Coating

Metal-coated plastic webs and papers play an important role in food packaging. Another important area of application of metal-coated web is the production of film capacitors for electrical and electronics applications.

Metal coating is carried out in vacuum web coating systems. The unit consists of two chambers, the winding chamber with the roll of web to be coated in the winding system and the coating chamber, where the evaporators are located. The two chambers are sealed from each other, except for two slits through which the web runs. This makes it possible to pump high gas loads from the web roll using a relatively small pumping set. The pressure in the winding chamber may be more than a factor of 100 higher than the pressure simultaneously established in the coating chamber.

During the coating process, the web, at a speed of more than 10 m/s, passes a group of evaporators consisting of ceramic boats from which aluminum is evaporated. To achieve the necessary aluminum coating thickness at these high web speeds, very high evaporation rates are required. The evaporators must be run at temperatures in excess of 1400°C. Thermal radiation of the evaporators, together with the heat of condensation of the growing layer, yields a considerable thermal load for the web. With the help of cooled rollers, the foil is cooled during and after coating so that it is not damaged during coating and has cooled significantly prior to winding.

During the entire coating process, the coating thickness is continuously monitored with an optical measuring system or by means of electrical resistance measurement devices. The measured values are compared with the coating thickness set points in the system, and the evaporator power is thus automatically controlled.

Optical Coatings

Vacuum coatings have a broad range of applications in production of ophthalmic optics, lenses for cameras, and other optical instruments, as well as a wide variety of optical filters and special mirrors. To obtain the desired transmission of reflection properties, at least 3, but sometimes up to 50, coatings are applied in the glass or plastic substrates. The coating properties, such as thickness and refractive index of the individual coatings, must be controlled very precisely and matched to each other.

Most of these coatings are produced using electron beam evaporators and single-chamber units. The evaporators are installed at the bottom of the chamber, usually with automatically operated crucibles, in which there are several different materials. The substrates are mounted on a rotating calotte above the evaporators. Application of suitable shielding, combined with relative movement between evaporators and substrates, results in a very high degree of coating uniformity. With the help of quartz coating thickness monitors and direct measurement of the attained optical properties of the coating system during coating, the coating process is fully controlled automatically.

One of the key requirements of coatings is that they retain their properties under usual ambient conditions over long periods of time. This requires the production of dense coatings, into which neither oxygen nor water can penetrate. Using glass lenses, this is achieved by keeping the substrates at temperatures up to 300°C during coating by means of radiation heaters. However, plastic lenses, as those used in eyeglass optics, are not allowed to be heated above 80°C.

To obtain dense, stable coatings, these substrates are bombarded with argon ions from an ion source during coating. Through ion bombardment, the right amount of energy is applied to the growing layer so that the coated particles are arranged on the energetically most favorable lattice sites, without the substrate temperature

V

reaching unacceptably high values. At the same time, oxygen can be added to the argon. The resulting oxygen ions are very reactive and ensure that the oxygen is included in the growing layer as desired.

Glass Coating

Coated glass plays a major role in a number of applications such as heat-reflecting coating systems on windowpanes to lower heating costs; solar protection coatings to reduce air-conditioning costs in countries with high-intensity solar radiation; coated car windows to reduce the heating-up of the interior; and mirrors used both in the furniture and the automobile industries.

The individual glass panes are transported into an entrance chamber at atmospheric pressure. After the entrance valve is closed, the chamber is evacuated with a forepump set. As soon as the pressure is low enough, the valve to the evacuated transfer chamber can be opened. The glass pane is moved into the transfer chamber and from there at constant speed to the process chambers, where coating is carried out by means of sputter cathodes. On the exit side, there is, in analogy to the entrance side, a transfer chamber in which the pane is held until it can be transferred out through the exit chamber.

Most of the coatings consist of a stack of alternative layers of metal and oxide. Because metal layers may not be contaminated with oxygen, the individual process stations have to be vacuum isolated from each other and from the transfer stations. To avoid frequent and undesirable starting and stopping of the glass panes, the process chambers are vacuum separated through so-called "slit locks," that is, constantly open slits combined with an intermediate chamber with its own vacuum pump. The gaps in the slits are kept as small as technically possible to minimize clearance and therefore conductance as the glass panes are transported through them. The pumping speed at the intermediate chamber is kept as high as possible to achieve a considerably lower pressure in the intermediate chamber than in the process chambers. This lower pressure greatly reduces the gas flow from a process chamber via the intermediate chamber to the adjacent process chamber. For very stringent separation requirements, it may be necessary to place several intermediate chambers between two process chambers.

The glass coating process requires high gas flows for the sputter processes as well as low hydrocarbon concentration. Turbomolecular pumps are used almost exclusively because of their high pumping speed stability over time.

While the transfer and process chambers are constantly evacuated, the entrance and exit chambers must be periodically vented and then evacuated again. Because of the large volumes of these chambers and the short cycle times, a combination of rotary vane pumps and Roots pumps is typically used to provide the necessary pumping speed.

Data Storage Disks

Coatings for magnetic- or magneto-optic data storage media usually consist of several functional coatings that are applied to mechanically finished disks. Most disks must be coated on both sides, and there are substantially greater low-particle contamination requirements as compared to glass coating. The sputter cathodes in the process stations are mounted on both sides of the carrier so that the front and back of the disk can be coated simultaneously.

An entirely different concept is applied for coating of single disks. In this case, the different process stations are arranged in a circle in a vacuum chamber. The disks are transferred individually from a magazine to a star-shaped transport arm. The transport arm cycles one station farther after each process step and in this way transports to substrates from one process station to the next.

During cycling, all processes are switched off and the stations are vacuum linked to each other. As soon as the arm has reached the process position, the individual stations are separated from each other by closing seals. Each station is pumped by means of its own turbomolecular pump, and the individual processes are started. By sealing off the process stations, excellent vacuum separation of the individual processes can be achieved. However, since the slowest process step determines the cycle interval, two process stations may have to be dedicated for particularly time-consuming processes.

Vacuum Refining

Melting in a vacuum to remove gaseous contaminants from the metal.

Vacuum Residue

The residue from vacuum distillation of crude oil.

Vacuum Sintering

Sintering of ceramics or metals at subatmospheric pressure.

Vacuum Sintering Furnace

A furnace wherein sintering of ceramics or metals is conducted in a vacuum. The furnace may be of a design either for batch sintering or for continuous sintering. See also *vacuum sintering*.

Vacuum Snapback Thermoforming

A *thermoforming* process for production of plastic items with external deep draws, such as auto parts and luggage. First, the sheet is clamped over the female cavity. Air pressure is then introduced through the channel and the base plate, stretching the plastic. When the material has been sufficiently stretched, the pressure is turned off, and vacuum is turned on, pulling the plastic into the mold. There are many variations of this method, some of which employ plug assists. See also *plug-assist forming*.

Vacuum Treatment/Melting

Treatment of solid or molten metal under vacuum. Vacuum treatment of solid metals, usually at high temperature, assists removal of dissolved gases. Vacuum treatment of molten metal removes gases and, depending on the vacuum, other contaminants. Bismuth, calcium, magnesium, and zinc and lead are removed from molten steel at about 10 kPa; antimony at about 100 Pa; and phosphorus, sulfur, and arsenic at 1 Pa.

Vacuum-Assisted Mold Processing

The use of atmospheric pressure to hold closed molds together during injection was the early process of vacuum-assisted resin injection (VARI). Adding vacuum has enabled resin transfer molding (RTM) to challenge compression molding and autoclaving systems capable of making the best high-performance composites. Vacuum is used in two ways. First, it mixes resin and hardener under a 91 Pa vacuum just prior to injection. Using an impeller, it agitates the mixture to drive air to the surface where the vacuum removes it. Degassing, which takes about 2 h per tank, also removes volatiles at low-molecular-weight by-products.

Some companies place their RTM tools in a vacuum chamber rather than using a vacuum tool. The chamber creates a vacuum that does not vary, even as resin fills the tool. The hard vacuum pulls any air and water vapor off the preform and sucks resin into the mold.

This combination of degassed resin and vacuum keeps voids under 3% and often better. This ensures consistently high structural integrity because voids concentrate stresses that initiate fractures and cause premature failure. It takes only a 2% increase in voids to drain interlaminar shear strength 20% and flexural modulus 10%. The process matches equivalent compression molding and autoclaving fiber volumes and voids.

Compared with compression molding and autoclaving, VARI does not need to apply pressure over the entire skin surface to vanquish voids, simplifying curing. For example, the process can fabricate cores and reinforced skins in a single step rather than bonding them after fabrication.

More importantly, the process makes composites in fewer, more controllable steps. These resin injection and molding processes—RTM, VARI, vacuum resin-transfer molding (VRTM), and vacuum-assisted resin-transfer molding (VARTM)—are much simpler processes to use.

Each process step is also independent and controllable. In VRTM, air evacuation depends on only the vacuum and resin preparation depends on only the resin mixer. Preform production varies with automated fabric weaving and preform placement, whereas core manufacture depends on molding or a machining process. The cure depends on a programmable heat source.

VRTM composites also show excellent resistance to water, solvents, and chemicals. This is largely a function of resin type and surface finish. Rough surfaces pitted with micropores trap water and chemicals and act as tiny reaction chambers that set in motion their own destruction. VRTM yields parts with less than 20 μm root mean square (rms) porosity. VRTM can achieve this fine finish repeatedly on all surfaces, depending on the finish of the tool. For high-quality finishes, compression and autoclaving processes depend on uniform resin flow under pressure, which they cannot always maintain.

The main attraction of VRTM, despite its competitive properties, remains cost, where it offers real advantages over compression molding and autoclaving.

Another production process is low-cost VARTM infusion technology.

VARTM is becoming a manufacturing method of choice because of its ability to produce fairly large structures out of the autoclave with the high quality usually associated with higher-price processes.

Valence

A positive number that characterizes the combining power of an element for other elements, as measured by the number of bonds to other atoms that one atom of the given element forms applied chemical combination; hydrogen is assigned valence 1, and the valence is the number of hydrogen atoms, or their equivalent, with which an atom of the given element combines.

Valence Electrons

The electrons in the atom's outer shell, the number of which establishes the valency.

Valency

A measure of the proportions in which atoms combine. The valency of any element is the number of atoms that will combine with or

replace one atom of hydrogen. It is controlled by the number of electrons in the outer shell of the atom, the so-called valency electrons. These being the only electrons available for interactions with other atoms. See *interatomic bonding*.

Valve Alloys

Iron-, nickel-, and cobalt-base alloys are the principal materials for intake and exhaust valves and valve-seat inserts of reciprocating combustion engines. Requirements include resistance to adhesive wear, heat, corrosion, and fatigue. Intake valves for light-duty, lower-temperature service are made from plain carbon steels. Temperatures are generally less than 425°C in light-duty, spark-ignition engines and 500°C in heavy-duty ones. Low-alloy martensitic steels, high-alloy martensitic steels, and austenitic steels are used progressively as temperatures and pressures increase. Intake-valve seats are commonly hard faced with a seat-facing alloy for the most demanding applications. Exhaust valves require resistance to wear, seat-face burning or guttering, fatigue, and creep, the latest to present head doming or "tuliping." Operating temperatures are generally 700°C–760°C, with spikes as high as 850°C. Exhaust valves are typically made of austenitic stainless steels and, for the highest service temperatures, superalloys.

Valve alloys include 1541H as 1547 *carbon steels*; 3140, 4140H, 5150H, 8645, B16, and GM-8440 *low-alloy steels*; Sil 1, Sil XB, 422, and SUH 11M *martensitic stainless steels*; and 21-2N, 21-4N, 21-4N+Cb+W, 23-8N, Gaman H, and 302 HQ *austenitic stainless steels*. Among the *superalloys*, all nickel based, are Inconel 751, Nimonic 80A, Pyromet 31V, and Waspaloy. Titanium alloys Ti-6Al-4V and Ti-6Al-2Sn-4Zr-2Mo find limited specialty applications.

Iron-base alloys include M2 tool steel and vanadium-free M2, and Sil XB. The tool steels, which contained M_6C carbides, are more resistant to wear and heat than Sil XB, which contains iron and chromium carbides. Hardness, 38–52 Rockwell C at room temperature, falls only to 30–34.5 at 427°C and to 23.5–25 at 538°C. The tool steels are often used for exhaust applications and gasoline engines and intake applications in diesel engines.

Nickel alloys, most often used for diesel exhaust inserts, include GM 3550M, SAE J 610B, 13, and J 610B, 12. All of these nickel alloys are generally confined to exhaust applications, performing poorly as intake alloys because, perhaps, of the type of film formed at lower temperatures.

As a class, *cobalt alloys* are generally useful to somewhat higher temperatures (871°C) and also provide sulfidation resistance. They include Stellite 3, Alloy 21, Stellite 6, and Stellite 12. Tribaloy T400 has the advantage of the combined lubricity and hardness of the laves phase for greater wear resistance.

Van der Waals' Bond

A secondary bond arising from the fluctuating dipole nature of an atom with all occupied electron shells filled.

Vanadium and Alloys

An elementary metal (symbol V), vanadium is widely distributed and is a pale-gray metal with a silvery luster. Its specific gravity is 6.02, and it melts at 1780°C. It does not oxidize in the air and is not attacked by hydrochloric or dilute sulfuric acid. It dissolves with a blue color in solutions of nitric acid. It is marketed as 99.5% pure, and cast ingots, machined ingots, and buttons. The as-cast metal

V

has a tensile strength of 372 MPa, yield strength of 10 MPa, and an elongation of 12%. Annealed sheet has a tensile strength of 537 MPa, a yield strength of 455 MPa, and an elongation of 20%, and the cold-rolled sheet has a tensile strength of 827 MPa with an elongation of 2%. Vanadium metal is expensive but is used for special purposes such as for springs of high flexural strength and corrosion resistance.

Commercially important as an oxidation catalyst, vanadium also is used in the production of ceramics and as a colorizing agent. Studies have demonstrated the biological occurrence of vanadium, especially in marine species; in mammals, vanadium has a pronounced effect on heart muscle contraction and renal function.

Fabrication

Hot Working

Since vanadium oxidizes rapidly at hot-working temperatures, forming a molten oxide, it must be protected during heating. This is most easily accomplished by heating in an inert gas atmosphere. Other common practices have been found less suitable.

Vanadium ingots up to 152 mm in size have been successfully hot worked, but the degree of contamination is a modifying factor. Generally, the procedures used in working alloy steels apply.

In view of the difficulties involved in heating the metal, reheating is generally avoided and the starting temperature is a function of the amount of hot work to be accomplished and of the desired finishing temperature. Starting temperatures can range as high as 1260°C, and the finishing temperatures are limited by the beginning of recrystallization. Straightening is performed between 171°C and 427°C but not at room temperature.

Cold Working

Vanadium has excellent cold-working properties, provided that its surfaces are uncontaminated. They are, therefore, machined clean by removing between 0.50 and 1 mm.

Strip can be readily made from hot-rolled sections of 31 × 152 mm in cross section, and 0.25 mm material has been produced without and 0.03 mm with intermediate annealing. Where incipient cracking is observed, vacuum annealing at 899°C becomes necessary.

Extrusion is one of the most suitable fabricating methods for vanadium since warm extrusion followed by cold rolling or drawing avoids hot working with the troublesome heating step. At temperatures below 538°C, tube blanks 50.8 mm outside diameter × 6.4 mm wall thickness have been produced from hot-rolled and turned bars as well as from ingots.

Wires can be drawn from 9.5 mm diameter stock down to 0.025 mm, especially after copper plating. Reductions are usually 10% per pass.

In machining, vanadium resembles the more difficult stainless steel. Low speeds with light to moderate feed are used, and very light finishing cuts at higher speeds are possible.

Welding is not difficult, but contamination of the metal must be avoided by shielding from air by means of an inert gas, that is, argon.

Uses and Applications

The greatest use of vanadium is for alloying. Ferrovanadium, for use in adding to steels, usually contains 30%–40% vanadium, 3%–6% carbon, and 8%–15% silicon, with the balance iron, but may also be had with very low carbon and silicon. Vanadium–boron, for alloying steels, is marketed as a master alloy containing 40%–45% vanadium, 8% boron, 5% titanium, 2.5% aluminum, and the balance iron, but the alloy may also be had with no titanium. *Van-Ad* alloy, for adding

vanadium to titanium alloys, contains 75% vanadium and the balance titanium. It comes as fine crystals. The vanadium–columbium alloys containing 20%–50% columbium have tensile strengths above 689 MPa at 700°C, 482 MPa at 1000°C, and 275 MPa at 1200°C.

Vanadium salts are used to color pottery and glass and as mordants in dyeing. Red cake, of crystalline vanadium oxide, is a reddish-brown material, containing about 85% vanadium pentoxide, V_2O_5 , and 9% Na_2O , used as a catalyst and for making vanadium compounds. Vanadium oxide is also used to produce yellow glass; the pigment known as vanadium–tin yellow is a mixture of vanadium pentoxide and tin oxide.

Vanadium is used in the cladding of fuel elements in nuclear reactors because it does not alloy with uranium and has good thermal conductivity as well as satisfactory thermal neutron cross section.

Because the metal alloys with both titanium and steel, it has found application in providing a bond in the titanium cladding of steel. Also, the good corrosion resistance of vanadium offers interesting possibilities for the future; it has excellent resistance to hydrochloric and sulfuric acids and resists aerated salt water very well. But its stability in caustic solutions is only fair and, in nitric acid, inadequate.

Borides, Carbides, and Oxides

Vanadium boride, VB, has a melting point of 2100°C with oxidation at 1000°C–1100°C, density 5.1 g/cm³, Mohs hardness 8–9, and electrical resistivity 16 Ω cm. It is also formed as VB_2 .

Vanadium carbide, VC, has a density of 5.81 g/cm³ and is silver gray in color. It is chemically very stable; among the cold acids, it is attacked only by nitric acid. Below 499°C, Cl_2 reacts with VC. It burns in oxygen or air but is stable up to 2500°C with nitrogen. VC is harder than corundum.

Vanadium pentoxide, V_2O_5 , has a melting point of 690°C and is slightly soluble in water. V_2O_5 is used by the ceramic industry as coloring agents producing various tints of yellow and greenish yellow. Vanadium pentoxide is an excellent flux, and small amounts may be helpful in promoting vitrification of ceramic products. Vanadate glasses are relatively fusible when compared with other oxide types.

Vanadium Steel

Vanadium was originally used in steel as a cleanser but is now employed in small amounts, 0.15%–0.25%, especially with a small quantity of chromium, as an alloying element to make strong, tough, and hard low-alloy steels. It increases the tensile strength without lowering the ductility, reduces grain growth, and increases the fatigue-resisting qualities of steels. Larger amounts are used in high-speed steels and in special steels. Vanadium is a powerful deoxidizer in steels but is too expensive for this purpose alone. Steels with 0.45%–0.55% carbon and small amounts of vanadium are used for forgings, and cast steels for aircraft parts usually contain vanadium. In tool steels vanadium widens the hardening range, and by the formation of double carbides with chromium makes hard and keen-edge die and cutter steels. All these steels are classed as chromium–vanadium steels. The carbon–vanadium steels for forgings and castings, without chromium, have slightly higher manganese.

Vanadium steels require higher quenching temperatures than ordinary steels or nickel steels. SAE 6145 steel, with 0.18% vanadium and 1% chromium, has a fine grain structure and is used for gears. It has a tensile strength of 799–2013 MPa when heat treated, with Brinell hardness 248–566, depending on the temperature of drawing, and then an elongation of 7%–26%. In cast vanadium

steels, it is usual to have from 0.18% to 0.25% vanadium with 0.35% to 0.45% carbon. Such castings have a tensile strength of about 551 MPa and an elongation of 22%. A nickel–vanadium cast steel has much higher strength, but high-alloy steels with only small amounts of vanadium are not usually classed as vanadium steels.

Vapor

The gaseous form of substances that are normally in the solid or liquid state and can be changed to these states either by increasing the pressure or decreasing the temperature.

Vapor Blasting

A cleaning process in which components are scoured by an aqueous suspension of abrasive entrained in a high-velocity air stream. Same as *liquid honing*.

Vapor Degreasing

Degreasing of work in the vapor over a boiling liquid solvent, the vapor being considerably heavier than air. At least one constituent of the soil must be soluble in the solvent. Modifications of this cleaning process include vapor-spray-vapor, warm liquid-vapor, boiling liquid-warm liquid-vapor, and ultrasonic degreasing.

Vapor Deposition

See *chemical vapor deposition*, *physical vapor deposition*, and *sputtering*.

Vapor Plating

Deposition of a metal or compound on a heated surface by reduction or decomposition of a volatile compound at a temperature below the melting points of the deposit and the base material. The reduction is usually accomplished by a gaseous reducing agent such as hydrogen. The decomposition process may involve thermal dissociation or reaction with the base material. Occasionally used to designate deposition on cold surfaces by vacuum evaporation. See also *vacuum deposition*.

Vapor Pressure

The measure of the tendency of a material to release molecules to its surroundings. In liquids, the phenomenon is readily recognized as evaporation, but similar effects occur more slowly in solid materials.

Vapor-Deposited Coatings

These are thin single or multilayer coatings applied to base surfaces by deposition of the coating metal from its vapor phase. Most metals and even some nonmetals, such as silicon oxide, can be vapor deposited. Vacuum-evaporated films or vacuum-metallized films were produced by vacuum evaporation. In addition to vacuum evaporation, vapor-deposited films can be produced by ion sputtering, chemical-vapor plating, and a glow-discharge process. The first two are discussed under vacuum processing.

In the glow-discharge process, applicable only to polymer films, a gas discharge deposits and polymerizes the plastic film on the base material.

Applications

Vapor plating is not considered to be competitive with electroplating. Its chief use (present and future) is to apply coating materials that cannot be electroplated or cannot be applied in a nonporous condition by other techniques. Such materials include titanium, zirconium, columbium, tantalum, molybdenum, and tungsten and refractory compounds such as the transition metal carbides, nitrides, borides, and silicides. Vapor plating will also continue to be useful in the preparation of ultrahigh-purity metals and compounds for use in electronic applications and in alloy development.

A few of the main commercial uses of vapor plating are as follows:

1. The application of high-chromium alloy coatings to iron and steel articles by the displacement-diffusion coating process (known as pack chromizing), for abrasion resistance and for protection from corrosion by food products, strong oxidizing acids, alkalies, salt solutions, and gaseous combustion products at temperature up to about 800°C.
2. The application of molybdenum disilicide coatings to molybdenum by gas-phase siliconizing, for protection against air oxidation at temperatures between 800°C and 1700°C.
3. The preparation of ultrahigh-purity titanium, zirconium, chromium, thorium, and silicon by iodide vapor decomposition processes.
4. The preparation of junction transistors by the controlled diffusion of boron from boron halide into the surface of silicon or germanium wafers.
5. The preparation of oriented graphite plates and shapes (pyrolytic graphite), by the high-temperature pyrolysis of hydrocarbon gases, for use in rocket and missile applications.

In addition, the following coatings have been developed:

1. Tantalum coatings on iron and steel for corrosion resistance
2. Vanadized, tungstenized, and molybdenized iron for wear resistance
3. Tungsten coatings on copper x-ray and cyclotron targets
4. Conductive metallic coatings on glass, porcelain, aluminum, porous bodies, rubber, and plastics
5. Refractory metal coatings on copper wires
6. Oxidation-resistant carbide coatings on graphite tubes, nozzles, and vanes
7. Metallic coatings of all types on metallic and nonmetallic powders
8. Decorative, colored coatings on glass
9. High-purity boron, radium, vanadium, germanium, and aluminum

The displacement-diffusion plating processes, such as pack-chromizing, can plate uniformly somewhat larger pieces and more complex shapes with inaccessible areas. Sheets and rod up to 0.6–0.9 m in dimension have been coated, and no technical obstacles are seen to scaling up the processes to coat even larger pieces. The pack coating processes have the advantage of minimizing the problems of specimen support and warpage during plating.

Plating uniformity varies somewhat with the particular process used, with the shape of the object being plated, and with the attention

given to providing proper gas flow around the object. A variation in thickness of 10%–25% is usually obtained. However, some coating processes can be made self-limiting so that the variation in coating thickness is much less than this range.

Disadvantages

Vapor plating has the following disadvantages:

1. Relative instability and air and moisture sensitivity of most of the compounds used as plating agents
2. A tendency to produce nonuniform deposits due to unfavorable gas flow patterns around the work, or to uneven specimen temperature
3. Alteration of physical properties of the substrate due to the elevated processing temperatures
4. The possibility of poor coating quality arising from undesired side reactions in the plating process

In general, the materials used as plating compounds in vapor plating are relatively unstable and easily decomposed by air and moisture, thus rendering them more expensive and more difficult to store and handle than the compounds used in other plating techniques. Also, some of the metal carbonyls, hydrides, and organometallic compounds are highly toxic, and some of the hydrides of metal alkyls inflame spontaneously upon contact with air.

To develop optimal properties in deposits of many materials, the plating compounds, particularly the moisture-sensitive metal halides, must be purified and used without contamination from the atmosphere. This apparent disadvantage is sometimes put to good use, however, when intentional contamination of the coating atmosphere with nitrogen or moisture is used to produce harder deposits (e.g., of titanium or tantalum), or to reduce the codeposition of carbon (e.g., with molybdenum from the carbonyl).

Nonuniform plating may result in all vapor plating processes, except for the displacement diffusion process, if consideration is not given to the gas-flow pattern around, or through the article to be coated. The shape factor may also have to be taken into account in selecting the method of heating the article to avoid nonuniform deposition due to nonuniform heating of the part. These difficulties can be overcome in extreme cases by applying more than one coating and using a different direction of gas flow over the specimen for each application.

If necessary, the displacement-diffusion type of coating process can be carried out at very low gas flow rates (since solid-state diffusion is the rate-controlling factor) and still produce uniform coatings. For this reason, this type of coating process is ideally suited for coating large, or highly irregular objects, or large numbers of small objects.

The elevated processing temperatures required in vapor plating may produce undesired physical changes in the article, such as loss of temper, grain growth, warping, dimensional change, or precipitation or solution of alloying constituents. However, in many instances, a vapor-plating procedure can be selected that will avoid marked undesirable change.

Undesirable side reactions in vapor-plating processes must be watched for and avoided. A particularly troublesome one in plating from metal halide vapors is the interaction of the base material and the halide vapor to form lower-valent halides, either of the base material or of the coating vapor. If the substrate temperature is too low or the plating atmosphere too rich in plating vapor, these lower-valent halides will condense at the surface of the substrate, producing a plate underlaid or contaminated with halide salts.

Such deposits are always poorly adherent, porous, and sensitive to moisture. Incomplete reduction or decomposition of the plating vapor alone can produce the same result. Contamination of this type is less likely to occur when plating inert base materials such as graphite, glass, and some ceramics.

After having been plated in a hydrogen atmosphere, some metals such as tantalum, columbium, and titanium, with a strong affinity for hydrogen, must be vacuum annealed, or at least cooled in an inert-gas atmosphere to avoid excessive hydrogen absorption and embrittlement.

Also, carburization of the substrate may occur in processes employing the metal carbonyls to coat metals with a strong affinity for carbon, if the substrate temperature is too high. The metal of the deposit itself may be partially carburized in some cases, as when depositing molybdenum, chromium, and tungsten from their carbonyl vapors.

Vapor-Deposited Replica

A *replica* formed of a metal or a salt by the condensation of the vapors of the material onto the surface to be replicated.

Vapor-Liquid-Solid Process

A process that utilizes vapor feed gases and a liquid catalyst to produce solid crystalline whiskers, such as silicon carbide whiskers used in composite materials.

Vapor-Phase Inhibitors

Substances that release vapors that inhibit corrosion on neighboring metal surfaces in moist conditions. Various materials, often impregnated into paper, are used, but they tend to be material specific, protecting some metals but not protecting others or even promoting their attack.

Vapor-Phase Lubrication

A type of lubrication in which one or more gaseous reactants are supplied to the vicinity of the surface to be lubricated and that subsequently react to form a lubricious deposit on that surface.

Variability

The number of degrees of freedom of a heterogeneous phase equilibrium.

Variance

A measure of the squared dispersion of observed values or measurements expressed as a function of the sum of the squared deviations from the population mean or sample average.

Varistor

A material, such as zinc oxide (ZnO), having an electrical resistance that is sensitive to changes in applied voltage.

Varnish

(1) In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels, lubricating oils, or organic constituents of

bearing materials. Harder deposits are described as *lacquers*, and softer deposits are described as *gums*. (2) A transparent surface coating that is applied as a liquid and then changes to a hard solid; all varnishes or solutions of resinous materials in a solvent.

V-Bend Die

A die commonly used in press-brake forming, usually machined with a triangular cross-sectional opening to provide two edges as fulcrums for accomplishing *three-point bending*. See also the term *press-break forming*.

V-Brain Seal

A seal consisting of a ring or nested rings that have a V-shaped cross section and that are commonly made from elastomeric material. Spring loading is sometimes used to maintain contact between the seal and its meeting surface. It is normally used to seal against axial motion.

V-Cone Blender

A machine for blending metal powders that has two cone-shaped containers arranged in a V and open to each other. See also *blending*.

Vector Field

Same as a *resultant field*.

Vegard's Law

The relationship that states that the lattice parameters of substitutional solid solutions vary linearly between the values for the components, with composition expressed in atomic percentage.

Veil

An ultrathin mat for reinforcing plastics similar to a *surfacing mat*, often composed of organic fibers as well as glass fibers. See also *mat*.

Veining

(1) A sub-boundary structure in a metal but can be delineated because of the presence of a greater than average concentration of precipitate or solute atoms. (2) The fine lines on a metallographic specimen formed at the boundaries of subgrains.

Vello Process

A process for continuously drawing glass tubing (or cane) in which glass is fed downward to the draw through an annular orifice.

Vent (Metals)

A small opening in a foundry mold for the escape of gases.

Vent (Plastics)

A small hole or shallow channel in a mold that allows air or gas to exit as the plastic molding material enters.

Vent Cloth

A layer or layers of open-weave cloth used to provide a path for vacuum to "reach" the area over a *laminated* being cured, such that volatiles and air can be removed. Also causes the pressure differential that results in the application of pressure to the part being cured. Also called breather cloth.

Vent Mark

A small protrusion resulting from the entrance of metal into die vent holes.

Venting

In autoclave curing of a composite part or assembly, turning off the vacuum source and venting the vacuum bag to the atmosphere. The pressure on the part is then the difference between pressure in the autoclave and atmospheric pressure. In injection molding, gases evolve from the melt and escape through vents machined in the barrel or mold.

Verdigris

The green corrosion product formed on copper exposed to the atmosphere. It is usually copper sulfate but may also contain chlorides and carbonates depending on local pollution. Same as *patina*. Historically, the term was used for green pigments, particularly basic copper acetate.

Verification

Checking or testing an instrument to ensure conformance with the specification.

Verified Loading Range

In the case of testing machines, the range of indicated loads for which the testing machine gives results within the permissible variation specified.

Vermiculite Iron

Same as *compacted graphite cast-iron*.

Vermiculite

(1) A granular, clay mineral constituent that is used as a textural material in painting, as an aggregate in certain plaster formulations used in sculpture, or mixed with a resin to form a filler of relatively high compressive strength. (2) A mixture of hydrated silicates of aluminum, iron, and magnesium. On heating, it expands and fragments producing the low-density material commonly used as a thermal insulator and for other applications. See also *filler* (1).

Vermiculite is a foliated mineral employed in making plasters and board for heat, cold, and sound insulation, as a filler in caulking compounds, and for plastic mortars and refractory concrete. The mineral is an alteration product of *biotite* and other micas. It occurs in crystalline plates, specific gravity 2.3, and Mohs hardness 1.5. The color is yellowish to brown. Upon calcination at 954°C, vermiculite expands at right angles to the cleavage into threads with a vermicular motion like a mass of small worms; hence its name.

V

The corklike pellets of vermiculite used for insulating fill in house walls are called *mica pellets*. *Exfoliated mica* is a name for expanded vermiculite.

Vernier

A short auxiliary scale that slides along the main test instrument scale to permit more accurate fractional reading of the least main division of the main scale. See also *least count*.

Vertical Illumination

Light incident on an object from the objective side of an optical microscope so that smooth planes perpendicular to the optical axis of the objective appear bright. See also *objective* and *optical microscope*.

Vertical Position

The position of welding in which the axis of the weld is approximately vertical. See the term *welding position*.

Vertical Position (Pipe Welding)

The position of a pipe joint in which welding is performed in the horizontal position, and the pipe may or may not be rotated. See the terms *horizontal fixed position* (pipe welding) and *horizontal rolled position* (pipe welding).

Vertical Welding Position

At a position in which the weld run is approximately vertical. This is usually taken to mean a Vickers hardness test. A hardness test utilizing a diamond indenter that is thrust into the component by a known load and the size of the indentation provides a measure of the hardness. The standard indenter is a square-based pyramid with a 136° included angle and, on the standard machine, weights are hung on the machine to induce via a lever system, loads of up to 120 kg at the indenter. After the load has been applied for a few seconds, the indentation is measured by a suitable microscope usually attached to the machine. The hardness number could then be calculated as load per unit area of impression in kg/mm from where P is load in kg and d is the diagonal of the impression in mm. The hardness is independent of the load; but in practice, to keep the impression size within sensible limits and to maximize accuracy, the load is matched to the material, typically 30 kg for steels and 10 kg for many non-ferrous metals. Tables for standard loads relate diametral measurements to hardness. Vickers hardness results are commonly reported as Hardness-Vickers, abbreviated to HV, or as Hardness Diamond (HD) or Vickers Pyramid Number (VPN). For example, 212 HV₃₀ (or HD30 or VPN30), that is, indicates a hardness on the Vickers scale of 212. The subscript, 30, merely indicates the load in kilograms applied during the test, and, in most cases, it can be ignored as the tables used for the calculation make due allowance for the load applied. Variations on the basic theme include microhardness devices where extremely small loads are used to measure microscopical features and the Knoop tester that utilizes an elongated base pyramid for testing thin sheet on edge. Also, various portable devices have been developed for site use that utilize spring or hydraulic systems to apply the load.

VI Improver

An additive, usually a polymer, that reduces the variation in viscosity with temperature, thereby increasing the viscosity index of an oil.

Vibration Density

The apparent density of a powder mass when the volume receptacle is vibrated under specified conditions while being loaded. Similar to *tap density*. See also *apparent density* (1).

Vibratory Cavitation

Cavitation caused by the pressure fluctuations within a liquid, adduced by the vibration of a solid surface immersed in the liquid.

Vibratory Compaction

A powder compacting process where vibration of the die assembly is used in addition to the usual pressure.

Vibratory Finishing

A process for deburring and surface finishing in which the product and an abrasive mixture are placed in a container and vibrated.

Vibratory Mill

A *bull mill* wherein the comminution is aided by subjecting the balls or rods to a vibratory force. See also *comminution*.

Vibratory Polishing

A mechanical polishing process in which a metallographic specimen is made to move around the polishing cloth by imparting a suitable vibratory motion to the polishing system. See also *polishing* (4).

Vicat Softening Point

The temperature at which a flat-ended needle of 1 mm² (0.0015 in.²) circular or square cross section will penetrate a thermoplastic specimen to a depth of 1 mm (0.040 in.) under a specified load, using a uniform rate of temperature rise.

Vickers Hardness Number (HV)

A number related to the applied load and the surface area of the permanent impression made by a square-based pyramidal diamond indenter having included face angles of 136°, computed from

$$HV = 2P \sin \frac{\alpha/2}{d^2} = \frac{1.8544P}{d^2}$$

where

P is the applied load (kgf)

d is the mean diagonal of the impression (mm)

α is the face angle of the indenter (136°)

Vickers Hardness Test

A microindentation hardness test employing a 136° diamond pyramid indenter (Vickers) and variable loads, enabling the use of one hardness scale for all ranges of hardness—from very soft lead to tungsten carbide. Also known as diamond pyramid hardness test. See also *microindentation* and *microindentation hardness number*.

Vidicon

A camera tube in which a charge-density pattern is formed by photoconduction and stored on a photoconductor surface that is scanned by an electron beam.

VIM

See *vacuum induction melting*.

VIM-VAR

A production route for very high-quality steel. See *vacuum induction melting* and *vacuum arc remelting*.

Vinyl Acetate Ethylene

Since their introduction, vinyl acetate ethylene (VAE) copolymer emulsions have been a staple base for adhesive manufacturers. As the performance requirements within the packaging and construction markets have increased and diversified, so too has the use of these emulsions.

First, VAE copolymer emulsions offer a tremendous balance between performance properties and ease of use. The internal plasticization of the vinyl acetate with ethylene gives these emulsions adhesion to many difficult-to-adhere substrates, while the polyvinyl alcohol (PVOH) stabilization system provides for high wet tack, good setting speeds, and excellent machinability.

Second, manufacturers of VAE emulsions have continued to advance the performance capabilities of these materials. Available today are functionalized VAE systems for adhesion to metallized surfaces, a range of glass transition temperatures for specific film properties, low volatile organic compound emulsions for sensitive food packaging applications, and higher solids technologies as an alternative to non-water-based systems. With these new VAE copolymer emulsions, adhesive compounders are better able to address the ever-changing needs of the adhesive industry.

At last, these types of the VAE emulsions are made even more versatile by their ability to be compounded with other raw materials and polymer systems. The additional formulations that can result from their compatibility with plasticizers, residence, fillers, humectants, surfactants, polyvinyl alcohol, etc., can offer various improvements in adhesion, tack, heat/cold resistance, flame retardancy, and range.

Processing and Applications

A most recent advance in VAE emulsion technology has been the introduction of a PVOH-stabilized, ultrahigh-solids copolymer emulsion that is polymerized at 72% solids and a 2000 cps viscosity. Its composition, structure, and colloidal properties provide faster setting speeds, higher wet tack, and improved adhesion to difficult-to-adhere substrates that was thought possible for VAE emulsions a few years ago. These performance features are allowing adhesive compounders to broaden greatly the applications utilizing waterborne technologies.

Polyurethanes have been available as adhesives for quite some time and are commonly found in vacuum-forming in plastics-bonding operations within the automotive and footwear industries. During the last 5 years, waterborne urethane chemistry has undergone a significant transformation from solvent-borne or high cosolvent-containing polymer systems to 100% waterborne systems.

These aqueous polyurethane dispersions, like their solvent-borne counterparts, have some unique performance characteristics. They offer low heat reactivation temperatures, good adhesion to difficult-to-bond substrates, rapid green strength development, and a high-temperature heat resistance. However, they also have some significant drawbacks. They are low in solids, low in wet tack, slow drying, and relatively high in cost.

The blending of polymers to improve adhesive properties is already widely done in the industry. With the commercially available aqueous polyurethane dispersions on the market today, the opportunity exists to enhance the performance of ultrahigh-solids VAE emulsions through blending because these technologies are so complementary. They are both 100% waterborne, and the characteristics of the ultrahigh-solids VAE emulsion can compensate for the disadvantages of urethane with its speed of set, wet tack, and minimal water content.

Future

Through the blending of an ultrahigh-solids VAE emulsion with many of the commercially available aqueous polyurethane dispersions on the market today, adhesive compounders can create a new class of stable high-performance waterborne adhesives.

Depending on the urethane grade selected and the level incorporated in the blend, the performance properties of the ultrahigh-solids VAE emulsion is dramatically enhanced in several areas:

- Cohesive strength
- Adhesion (vinyl)
- Heat sealability
- Cross-linker performance

Vinyl Acetate Plastics

Plastics based on polymers of vinyl chloride or copolymers of vinyl chloride with other monomers, the vinyl chloride having the greatest amount of mass.

Vinyl Esters

A class of thermosetting resins containing esters of acrylic and/or methacrylic acids, many of which have been made from epoxy resin. Cure is accomplished, as with unsaturated polyesters, by copolymerization with other vinyl monomers, such as styrene. Glass-reinforced vinyl esters are used in corrosion-resistant products, such as piping and storage tanks, used in the pulp and paper, chemical process, wastewater, and mining industries.

Vinyl Resins and Plastics

These are a group of products varying from liquids to hard solids, made by the polymerization of ethylene derivatives, employed for finishes, coatings, and molding resins, or it could be made directly by reacting acetic acid with ethylene and oxygen. In general, the term *vinyl* designates plastics made by polymerizing vinyl chloride, vinyl acetate, or vinylidene chloride, but may include plastics

V

made from styrene and other chemicals. The term is generic for compounds of the basic formula $RCH=CR'CR''$. The simplest are the polyesters of vinyl alcohol, such as vinyl acetate. This resin is lightweight with a specific gravity of 1.18, and is transparent, but it has poor molding qualities and its strength is no more than 34 MPa. But the vinyl halides, $CH_2=CHX$, also polymerize readily to form vinylite resins, which mold well, have tensile strengths up to 62 MPa, high dielectric strength and high chemical resistance, and a widely useful range of resins are produced by copolymers of vinyl acetate and vinyl chloride.

The possibility of variation in the vinyl resins by change of the monomer, copolymerization, and difference in compounding is so great that the term *vinyl resin* is almost meaningless when used alone. The resins are marketed under a continuously increasing number of trade names. In general, each resin is designed for specific uses but is not limited to those uses.

Vinyl Alcohol

Vinyl alcohol, $CH_2=CHOH$, is a liquid boiling at 35.5°C. Polyvinyl alcohol is a white, odorless, tasteless powder which on drying from solutions forms a colorless and tough film. The material is used as a thickener for latex, in chewing gum, and for sizes and adhesives. It can be compounded with plasticizers and molded or extruded into tough and elastic products. Hydrolyzed polyvinyl alcohol has greater water resistance, higher adhesion, and its lower residual acetate gives lower foaming. Soluble film, for packaging detergents and other water-dispersible materials to eliminate the need of opening the package, is a clear polyvinyl alcohol film. Textile fibers are also made from polyvinyl alcohol, either water soluble or insolubilized with formaldehyde or another agent. Polyvinyl alcohol textile fiber is hot-drawn by a semimelt process and insolubilized after drawing. The fiber has a high degree of orientation and crystallinity, giving good strength and hot-water resistance.

Vinyl alcohol reacted with an aldehyde, and an acid catalyst produces a group of polymers known as vinyl acetal resins, and separately designated by type names, as polyvinyl butyral and polyvinyl formal. The polyvinyl alcohols are called **Solvvars**, and the polyvinyl acetates are called **Gelvas**. The vinyl ethers range from vinyl methyl ether, to vinyl ethylhexyl ether, from soft compound so hard resins. Vinyl ether is a liquid that polymerizes, or that can be reacted with hydroxyl groups to form acetyl resins. Alkyl vinyl ethers are made by reacting acetylene with an alcohol under pressure, producing methyl vinyl ether, ethyl vinyl ether, or butyl vinyl ether. They have reactive double bonds that can be used to copolymerize with other vinyls to give a variety of physical properties. The polyvinyl formals, **Formvars**, are used in molding compounds, wire coatings, and impregnating compounds. They are one of the toughest of the thermoplastics.

Plastisol

A plastisol is a vinyl resin dissolved in a plasticizer to make a pourable liquid without a volatile solvent for casting. The poured liquid is solidified by heating. Plastigels are plastisols to which a gelling agent has been added to increase viscosity. The polyvinyl acetals, **Alvars**, are used in lacquers, adhesives, and phonograph records. The transparent polyvinyl butyrals, **Butvars**, are used as interlayers of laminated glass. They are made by reacting polyvinyl alcohol with butyraldehyde. Vinal is a general name for vinyl butyral resin used for laminated glass.

Vinyl Acetate

Vinyl acetate is a water-white mobile liquid with boiling point 70°C, usually shipped with a copper salt to prevent polymerization in transit. It may be polymerized in benzene and marketed in solution, or in water solution for use as an extender for rubber, and for adhesives and coatings. The higher the polymerization of the resin, the higher the softening point of the resin. Polyvinyl acetate resin is a colorless, odorless thermoplastic with density of 1.189, unaffected by water, gasoline, or oils, but soluble in the lower alcohols, benzene, and chlorinated hydrocarbons. Polyvinyl acetate resins are stable to light, transparent to ultraviolet light, and are valued for lacquers and coatings because of their high adhesion, durability, and ease of compounding with gums and resins. Residents of low molecular weight are used for coatings, and those of high molecular weight for molding. Vinyl acetate will copolymerize with maleic acrylonitrile or acrylic esters. With ethylene, it produces a copolymer latex of superior toughness and abrasion resistance for coatings.

Vinyl Benzoate

Vinyl benzoate is an oily liquid that can be polymerized to form resins with higher softening points than those of polyvinyl acetate, but that are more brittle at low temperatures. These resins, copolymerized with vinyl acetate, are used for water-repellent coatings. Vinyl crotonate is a liquid of specific gravity of 0.9434. Its copolymers are brittle resins, but it is used as a cross-linking agent for other resins to raise the softening point and to increase abrasion resistance. Vinyl formate is a colorless liquid that polymerizes to form clear polyvinyl formate resins that are harder and more resistant to solvents than polyvinyl acetate. The monomer is also copolymerized with ethylene monomers to form resins for mixing in specialty rubbers. Methyl vinyl pyridine is used in making resins, fibers, and oil-resistant rubbers. It is a colorless liquid boiling at 64.4°C. The active methyl groups give condensation reactions, and it will copolymerize with butadiene, styrene, or acrylonitrile. Polyvinyl carbazole, under the name of **Luvican**, is used as a mica substitute for high-frequency insulation. It is a brown resin, softening at 150°C.

Vinyl Chloride

Vinyl chloride, also called ethenyl chloride and chloroethylene, produced by reacting ethylene with oxygen from the air and ethylene dichloride, is the basic material for the polyvinyl chloride resins. It is a gas. The plastic was produced originally for cable installation and for tire tubes. The tensile strength of the plastic may vary from the flexible resins with about 20 MPa to the rigid resin with the tensile strength of 62 MPa and Shore hardness of 90. The dielectric strength is high, up to 52×10^6 V/m. It is resistant to acids and alkalies. Unplasticized polyvinyl chloride is used for rigid chemical-resistant pipe. Polyvinyl chloride sheet, unmodified, has a tensile strength of 57 MPa, flexural strength 86 MPa, and a light transmission of 78%.

Polyvinyl Chloride

Polyvinyl chloride (PVC) is a thermoplastic polymer formed by the polymerization of vinyl chloride. Resins of different properties can be made by variations in polymerization techniques. These resins can be compounded with plasticizers, color, mineral filler, etc., and processed into usable forms, varying widely in physical and electrical properties, chemical resistance, and processing versatility in coloring and design. Compared with other thermoplastics of comparable cost, articles produced from the vinyl chloride plastics have

outstanding chemical, flame, and abrasion resistance, tensile properties, and resistance to heat distortion.

PVC homopolymer resins, the largest single type of vinyl chloride-containing plastics, are produced by several methods of polymerization:

1. *Suspension*: The largest-volume method that produces resins for general purpose use, processed by calendering, injection molding, extrusion, etc.
2. *Mass or solution*: Produces fine particle size resins used principally for calendering and solution coating.
3. *Emulsion*: Produces extremely fine particle size resins used for the preparation of liquid plastisols or organosols for use in slush molding, coatings, and foam.

The two largest-volume members of the family of vinyl chloride polymers are the pure polyvinyl chloride or homopolymer resins and the vinyl chloride-vinyl acetate copolymers containing approximately 5%–15% vinyl acetate.

Types of Vinyls/PVCs

Rigid Vinyls

Products made from rigid vinyls are perhaps of most interest in the engineering field. Rigid materials can be prepared by calendering, extrusion, injection molding, transfer molding, and solution casting processes. Rigid PVC products are available in sheets, films, rods, pipes, profiles, valves, nuts and bolts, etc. The products can be machined easily with wood and metal-working tools.

Sheets or other forms can be conventionally welded by hot-air guns, using extruded welding rods of essentially the same composition as that of the sheet. The welded joints have strength equal to that of the base material. Rigid sheets can be thermoformed into many intricate shapes by several different thermoforming techniques such as vacuum forming and ring and plug forming. Rigid pipe can be threaded and joined like steel pipe or sealed with adhesives in a manner similar to the sweating of copper pipe. Vinyl pipe is being used increasingly in waterworks, the petroleum industry, in natural gas distribution, irrigation, hazardous chemical application, and food processing.

Rigid vinyl made from vinyl acetate–vinyl chloride copolymers is prominent in sheeting used for thermoforming for such items as maps, packaging, advertising displays, and toys. Rigid materials made from homopolymer vinyl chloride resins are used in heavier structural designs, for example, pipe, pipe valve, heavy panels, electrical ducting, window and door framing parts, architectural moldings, gutters, downspouts, and automotive trim. In these fields, rigid vinyls compete with aluminum and other metals. Rigid vinyl products made from homopolymer resins are available in two types: type I, or unmodified PVC, is approximately 95% PVC and has outstanding chemical resistance but low impact strength. Type II PVC, containing 10%–20% of a resinous or rubbery polymeric modifier, has improved impact strength but reduced chemical resistance.

Flexible Vinyls

Flexible vinyl products are produced by the same general methods used for rigid vinyl products. Flexibility is achieved by the incorporation of plasticizers (mainly high-boiling organic esters) with the vinyl polymer. By proper choice of plasticizer type, flexible products can be obtained that excel in certain specific properties such as gasoline and oil resistance, low temperature flexibility, and flame resistance.

The flexible sheeting and film can be fabricated by heat sealing to itself or other substrates by induction or high-frequency methods, solvent sealing, sewing, etc. Flexible vinyl film and sheeting find applications in upholstery, packaging, agriculture, etc. The corrosion resistance of vinyl sheeting makes it ideal for a pipe wrap to prevent corrosion of underground installations. Flexible extensions in many different shapes and forms have applications as insulating and jacketing on electrical wire and cable, refrigerator gaskets, weather stripping, upholstery, and shoe welding. Injection-molded flexible vinyl products are used as shoes, electrical plugs, and installation of various sorts.

Abrasion and stain resistance, coupled with unlimited coloring and design possibilities, have made flexible vinyl flooring one of the largest items in the floor-covering field. The major revolution in vinyl flooring is the greater emphasis on the use of relatively low to very low molecular weight homopolymer resins in place of the more expensive vinyl chloride–vinyl acetate copolymers.

Coatings

Coatings based on PVC polymers and copolymers can be applied from solutions, latex, plastisols, or organosols. Plastisols are liquid dispersions of fine particle size emulsion PVC in plasticizers. Organosols are essentially the same as plastisols but contain a volatile liquid organic diluent to reduce viscosity and facilitate processing. In many coating operations, conventional paint-spraying equipment is used. In other techniques, articles can be dip-, knife-, or roller-coated. Plastisols and organosols are used extensively for dip coating of wire products such as household utensils and knife coating of fabrics and paper. Plastisol and organosols products can be varied from hard (rigidsols) to very soft (vinyl foam). Vinyl coatings are used for a variety of applications requiring corrosion and/or abrasion resistance.

Production coatings with vinyl plastics involve a fluidized-bed technique. A metallic object, heated to 204°C–260°C, is immersed in a bed of finely ground plastic which is “fluidized” by air entering the bottom of the container. Articles can be coated by this method to a thickness of 7–60 mils. Both rigid and plasticized vinyls can be applied by this method.

Vinyl-Metal Laminates

These products are made by direct lamination of free processed, embossed, and designed vinyl sheet to metal, or continuous plastisol coating of metal sheet followed by fusing or curing of the plastisol and subsequent embossing. In the former process, the vinyl can be laminated to both sides of the metal sheet. Steel, aluminum, magnesium, brass, and copper have been used. The hardness, elongation, general properties, and thickness of the vinyl can be modified within wide limits to meet particular needs.

These laminates are dimensionally stable below 100°C and combine the chemical and flame resistance, decorative and design possibilities of vinyl with the rigidity, strength, and fabricating attributes of metals. The vinyl-metal laminates can be worked without rupture by many of the metalworking techniques, such as deep-drawing, crimping, stamping, punching, shearing, and reverse-bending. Disadvantages are inability to spot-weld, and lack of covering of metal edges, which is necessary where severe exposure conditions are encountered. Vinyl-metal laminates find use in appliance cabinets, machined housings, lawn and office furniture, automotive parts, luggage, chemical tanks, etc. The cost of these laminates is comparable to some lacquered metal surfaces.

Vinylidene Chloride Plastics

Vinylidene chloride plastics are derived from ethylene and chlorine polymerized to produce a thermoplastic with softening point

V

of 116°C–138°C. The resins are noted for their toughness and resistance to water and chemicals. The molded residents have a specific gravity of 1.68–1.75, tensile strength 27–48 MPa, and a flexural strength of 103–117 MPa. *Saran* is the name of vinylidene chloride plastic, extruded in the form of tubes for handling chemicals, brines, and solvents to temperatures as high as 135°C. It is also extruded into strands and woven into a box-weave material as a substitute for rat-tan for seating. Saran latex, a water dispersion of the plastic, is used for coating and impregnating fabrics. For coating food-packaging papers, it is waterproof and greaseproof, odorless, and tasteless, and gives the papers a high gloss. Saran is also produced as a strong transparent film for packaging. Saran bristles for brushes are made in diameters from 0.025 to 0.051 cm.

Applications

The two largest-volume applications are in upholstery made from monofilaments and film for food packaging. Other uses are in window screening (monofilaments), paper and other coatings, pipe and pipe linings, and staple fiber.

Saran pipe and Saran-lined metal pipe are of interest in the engineering field. Saran-lined pipe is prepared by swaging an oversize metal pipe on an extruded Saran tube. These products can be installed with ordinary piping tool. Fittings and valves lined with Saran and flange joints with Saran gaskets are available. Vinylidene chloride–acrylonitrile copolymer has applications as coatings for tank car and ship-hold linings. Lacquers of these polymers are used in cellophane coatings yielding a product with the low-moisture vapor permeability of vinylidene chloride polymers plus the handling ease of cellophane. The lacquers are also used for paper coatings, dip coatings, and sprayed packaging. Vinylidene chloride copolymers in latex form are used in paper coatings and specialty paints.

Vinylidene Fluoride

Vinylidene fluoride has a high molecular weight, about 500,000. It is a hard, white thermoplastic resin with a slippery surface and has a high resistance to chemicals. It resists temperatures up to 343°C and does not become brittle at low temperatures. It extrudes easily and has been used for wire insulation, gaskets, seals, molded parts, and piping.

Vinylidene Chloride Plastics

Plastics based on polymer resins made by the polymerization of vinylidene chloride or copolymerization of vinylidene chloride with other unsaturated compounds, the vinylidene chloride being the greatest amount by weight.

Virgin Filament

An individual *filament* that has not been in contact with any other fiber or any other hard material.

Virgin Material

A plastic material in the form of pellets, granules, powder, flock, or liquid that is not been subjected to use or processing other than that required for its initial manufacture.

Virgin Metal

Metal produced from ore and not contaminated by remelted scrap. Same as *primary metal*.

Viscoelastic

The phenomenon whereby the reversible relationship between stress and strain is time related.

Viscoelasticity

A property involving a combination of elastic and viscous behavior that makes deformation dependent upon both temperature and strain rate. A material having this property is considered to combine the features of a perfectly elastic solid and a perfect fluid.

Viscosity

The bulk property of a fluid, semifluid, or semisolid substance that causes it to resist flow. Viscosity is defined by the equation

$$\eta = \frac{\tau}{(dv/ds)}$$

where

τ is the shear stress

v is the velocity

s is the thickness of an element measured perpendicular to the direction of flow

(dv/ds) is known as the rate of shear

Newtonian viscosity is often called dynamic viscosity, or absolute viscosity. Kinematic viscosity, or static viscosity (ν), is the ratio of dynamic viscosity (η) to density (ρ) at a specified temperature and pressure ($\nu = \eta/\rho$). Recommended units of measure for dynamic viscosity are the Pascal second (Pa s) in SI units and poise (P) in English units. Recommended units of measure for kinematic viscosity are square meters per second (m²/s) in SI units and the Stoke, or centistoke (cSt) in English units.

Viscosity Coefficient

The shearing stress tangentially applied that will induce a velocity gradient in a material.

Viscosity Index (VI)

A commonly used measure of the change in viscosity of a fluid with temperature. The higher the viscosity index, the smaller the relative change in viscosity with temperature. Two different indices are used; the earlier usage applies to oils having a VI from 0 to 100. Extended VI applies to oils having a VI of at least 100. It compares the oil with a reference oil of VI 100.

Viscous

Possessing viscosity. This term is frequently used to imply high viscosity.

Viscous Deformation

Any portion of the total deformation of a body that occurs as a function of time when load is applied but that remains permanently when the load is removed generally referred to as *elastic deformation*.

Viscous Flow

A mode of plastic deformation, particularly early stages of creep, in which the stress-strain relationship is time dependent, and in which tensile loading does not initiate necking.

Viscous Friction

See *fluid friction*.

Visible

Pertaining to radiant energy in the electromagnetic spectral range visible to the normal human eye (–380 to 780 nm).

Visible Radiation

Electromagnetic radiation in the spectral range visible to the human eye (–380 to 780 nm).

Visible-Light-Emitting Diode

An optoelectronic device containing a semiconductor junction that emits visible light went forward biased. The material is usually gallium phosphide or gallium arsenide phosphide. See also *gallium* and *gallium compounds*.

Visual Examination

The qualitative observation of physical characteristics, observed by using the unaided eye or perhaps aided by the use of a simple hand-held lens (up to 10×).

Vitreous

(1) Partially or completely comprised of a glass; often containing solid particles distributed therein. (2) Glasslike, particularly vitreous enamels applied by fusing a glass powder on the surface of a (usually steel) component.

Vitreous Enamel

See *porcelain enamel*.

Vitrification

(1) The formation of a glassy or noncrystalline material. (2) The characteristic of a clay product resulting when the kiln temperature is sufficient to fuse grains and close the surface pores, forming an impervious mass. (3) The progressive reduction in porosity of a ceramic composition as a result of heat treatment, or the process involved.

Vitrify

To render vitreous, generally by heating; usually, achieving enough glassy phase to render impermeable.

Vitriol Sulfuric Acid

A_2SO_4 .

V-Mixer

A machine for mixing metal powders that has two cylindrical containers arranged in the shape of a V and open to each other. See also *mixing*.

Void

A cavity within a solid or liquid.

Void (Composites)

Air or gas that has been trapped and cured into a laminate. Porosity is an aggregation of microvoids. Voids are essentially incapable of transmitting structural stresses or nonradiative energy fields.

Void (Metals)

(1) A *shrinkage cavity* produced in castings or weldments during solidification. (2) A term generally applied to paints to describe *holidays*, holes, and skips in a film.

Void Content

Volume percentage of voids, usually less than 1% in a properly cured composite. The experimental determination is indirect, that is, it is calculated from the measured density of a cured laminate and the “theoretical” density of the starting material.

Voidage

The measure, usually a volume percentage, of voids in a material.

Volatile Content

The percentage of *volatiles* that is driven off as a vapor from a plastic or an impregnated reinforcement.

Volatile Organic Compound

Many efforts have been underway regarding the biological control of volatile organic compound (VOC) emissions.

Water-based and hot-melt adhesives and coatings have been developed and evaluated extensively, but they are not satisfactory for all applications and may require solvent-based cleaners and primers. Various developments have shown how biological treatment can reduce solvent levels in air emissions and focuses in particular on footwear production. It is, however, applicable to all industries using organic solvents.

For example, the U.K. Environmental Protection Act 1990 sets a 5 metric tons/year adhesive solvent usage threshold, above which processes are subject to local authority air pollution control. This regulation apparently affects manufacturing plants producing as few as 5000 pairs of shoes per week.

By June 1998, shoemakers and material suppliers were set to meet an emission limit of 50 mg/m³ measured as carbon, or a stringent mass emission control regime of 20 g/pair for footwear; similar controls have been initiated throughout Europe.

V

Catalytic combustion has been shown to be technically effective, but involves high capital and running costs. For example, adsorption on activated carbon is an established technique, but apparently it is unsuitable for the mixed cocktail of solvents in footwear production. Biological treatment processes have shown to be less costly and more suitable for arresting emissions of moderate concentration at ambient temperature, as found in shoe factory exhausts.

Biological treatment has been shown suitable for halting VOC emissions from the manufacturing industry with an on-site biological treatment unit set up to demonstrate VOC abatement.

Process

The process biologically breaks down VOCs into biomass by mineralization and utilization of the carbon; the by-products of breakdown are carbon dioxide and water vapor. Within the system, microorganisms grow as a biofilm on selected media where they produce enzymes to break down the VOC contaminants. Liquid is continuously recirculated to solubilize the solvents from the contaminated inlet gas. Water is sprayed evenly where the microorganisms oxidize the solvents, and monitoring of the recirculation liquid for determinants, including pH, nitrogen, phosphorus, suspended solids, and so on apparently allows for tighter process control and greater removal efficiency.

In this system, there is a large interface between gas and liquid phases so that the bed can capture the compounds of poor solubility that are present in the off-gases. Inputs to the process include main water supply, electricity to run pumps, solenoid valves, and a programmable logic controller, as well as nutrients to maintain the biomass, including nitrogen, phosphate, sulfate, and trace elements that are added according to the carbon load to the reactor.

Although this process was used at a footwear manufacturing plant, biotechnology also has application within other industries producing low-concentration mixed solvent waste streams, where recovery is inappropriate and the capital and operating costs of thermal and catalytic systems can be prohibitively expensive. Examples include printing, painting, laminating, metal and leather finishing, and furniture coating.

In another example, the U.S. Navy studied a new environmentally safe paint coating for use on its fleet of helicopters. The three-shade flat, haze gray coats were sprayed on a new Navy fleet combat support helicopter. What makes the coating environmentally safe is the absence of VOCs that contribute to air pollution. The new coating eliminates the use of chemicals targeted by the federal government for reduction or elimination.

Normal Environmental Protection Agency (EPA)-compliant aircraft coatings currently use bT-fy that contain about 3.5 lb of VOC/gallon, whereas this new paint has zero VOC.

The zero-VOC paint was developed by Deft Coatings, Inc. This zero-VOC coating also offers a significant weight benefit compared to the current paint and is nonflammable.

The first zero-VOC-coated helicopter was tested and evaluated by the Navy to ensure that the new coating met stringent Military Standard requirements.

Volatiles

Materials, such as water and alcohol, in a sizing or resin formulation, that are capable of being driven off as a vapor at room temperature or slightly elevated temperature. See also *size*.

Volatilization

The conversion of a chemical substance from a liquid or solid state to a gaseous or vapor state by the application of heat, by reducing

pressure, or by a combination of these processes. Also known as *vaporization*.

Volt

The unit of potential difference or electromotive force in the meter-kilogram-second system, equal to the potential difference between two points for which 1 C of electricity will do 1 J of work in going from one point to the other. Symbolized V.

Voltage Alignment

A condition of alignment of an electron microscope so that the image expands or contracts symmetrically about the center of the viewing screen when the accelerating voltage is changed. See also *alignment*.

Voltage Drop

The amount of voltage loss from original input in a conductor of given size and length.

Voltage Efficiency

The ratio, usually expressed as a percentage, of the equilibrium-reaction potential in a given electrochemical process to the bath voltage.

Voltage Regulator

An automatic electrical control device for maintaining a constant voltage supply to the primary of a welding transformer.

Voltage Stress

That stress found within a material when subjected to an electrical charge.

Voltaic Cell

An electrolytic cell in which an electric current flows between a pair of electrodes that are immersed in an electrolyte and electrically connected externally.

Voltammetry

An electrochemical technique in which the current between working (indicator) electrodes and counterelectrodes immersed in an electrolyte is measured as a function of the potential difference between the indicator electrode and a reference electrode.

Volume Diffusion

One of the primary diffusion mechanisms during sintering. It is predominant for larger particles at higher temperatures, and its diffusion coefficient for the same conditions is smaller than that for grain boundary diffusion, and much smaller than that for surface diffusion. See also *grain boundary diffusion* and *surface diffusion*.

Volume Filling

Filling the volume of a die cavity or receptacle with loose powder, and striking off any excess amount.

Volume Fraction

Fraction of the constituent material, such as fibers in a composite material, based on its volume.

Volume Ratio

The volume percentage of solid in the total volume of a sintered body.

Volume Resistance

The ratio of the direct voltage applied to two electrodes in contact with or embedded in a specimen to that portion of the current between them that is distributed through the volume of the specimen.

Volume Shrinkage

The volumetric size reduction a powder compact undergoes during sintering. Contrast with *linear shrinkage*.

Volumetric Analysis

(1) Quantitative analysis of solutions of known volume, but unknown strength by adding reagents of known concentration onto a reaction end point (color change or precipitation) is reached; the most common technique is by *titration*. (2) A form of chemical analysis in which the material in question is dissolved in known concentration and the solution reacted with other solutions of suitable reagents and standardized concentration.

Volumetric Modulus of Elasticity

See *bulk modulus of elasticity*.

Volumetric Strain

The algebraic sum of the strains induced by the three principal stresses.

Von Laue Technique

See *back reflection x-ray technique*.

Vortex (Shedding) Fatigue

Fatigue cracking due to the shedding of vortices arising from the rapid flow of fluid over a surface. The example usually quoted is of slender metal chimney stacks that in strong winds shed vortices on alternate sides causing the stack to vibrate across the airstream causing fatigue cracking. The effect may be countered by fitting spiral fins around the stack.

Voxel

Shortened term for volume element. In computed tomography, the volume within the object that corresponds to a single pixel element in the image. The box-shaped volume defined by the area of the pixel and the height of the slice thickness. See also *pixel*.

Vulcanization

A chemical reaction in which the physical properties of a rubber are changed in the direction of decreased plastic flow, less surface tackiness, and increased tensile strength by reacting it with sulfur or other suitable agents. See also *self-vulcanizing*.

Vulcanize

To subject to *vulcanization*.

Vulcanized Fiber

Vulcanized fiber is a pure, dense, cellulosic material with good electrical insulating properties and high mechanical strength. It is half the weight of aluminum, easily machined and formed, and is used for parts such as for barriers, abrasive-disk backing, high-strength bobbin heads, materials-handling equipment, railroad-track insulation, and athletic guards.

Forms

Most manufacturers provide vulcanized fiber in the form of sheets, coils, tubes, and rods. Sheets are made in a thickness of 0.06–50.8 mm, approximately 1.2×2 m in size, or in rolls and coils from 0.06 to 2.3 mm thick. Tubes are made in the outside diameter range of 4.7–111.5 mm, and rods are produced 2.3–50.4 mm in diameter.

Sheets can be machined and formed to produce a variety of useful shapes for insulating or shielding purposes. Sheets, tubes, and rods can be machined using standard practices for cutting, punching, tapping, milling, shaping, sanding, etc.

Properties

Vulcanized fiber possesses a versatile combination of properties, making it a useful material for practically all fields. It has outstanding arc resistance, high structural strength per unit area, and can be formed and machined. In thin sections, it possesses high tear strength, smoothness, and flexibility. In heavier thicknesses, it resists repeated impact and has high tensile, flexural, and compressive strength.

The material is unaffected by normal solvents, gasoline, and oils and therefore is recommended for applications where a structural support is required in the presence of these materials.

Moisture absorption is high, and dimensional stability is affected by conditions of humidity when not protected by moisture-resistant coatings.

Vulcanized fiber is produced in 13 basic grades and numerous special grades to meet specific application requirements.

Applications

Vulcanized fiber serves as the insulating material in a signal block for railroad track insulations. At the end of a signal station, the rails are completely insulated from the next adjoining section to form what is termed a *block*. The two meeting rails and the coupling fixtures are insulated with formed parts made from vulcanized fiber. This junction is effective while absorbing the repeated impact from trains under all weather conditions.

Vulcanized fiber offers durability, ease of fabricating, excellent wear characteristics, and lightness of weight for materials-handling and luggage applications. The materials-handling equipment resists

V

scuffing, battering, denting, rusting, and other general wearing conditions and provides protection by its hardness and resilience.

Formed pieces of vulcanized fiber offer outstanding service as arc barriers in circuit breakers. The arc-resistant properties of vulcanized fiber prevent a breakdown when the circuit breaker is subjected to an overload. The formed barrier is tested to take higher electrical loads than the maximum that can be produced by the circuit and, since repeated circuit breaks will not affect the performance of vulcanized fiber, the need for replacement is negligible.

Peerless control tape is used for programming data, processing equipment, or automatic machining equipment. The special properties that give this material outstanding service life are high tensile strength, high tear strength, low stretch, and good abrasive resistance.

Flame-resistant vulcanized fiber gives designers a structural material that can be used in those applications requiring a non-burning material and reduces fire hazard by containing a fire at its source. Flame-retardant parts serve as barriers in electrical equipment, materials-handling equipment, and wastebaskets.

Chemistry

Vulcanized fiber is produced by the chemical action of zinc chloride solution on a saturating grade of absorbent paper when processed under heat and pressure. The action of the zinc chloride converts the cellulosic fibers to a dense, homogeneous structure producing a laminated material that is refined to a chemically pure form. Final processing consists of drying to the proper moisture content and applying the proper calender to give smoothness and uniformity of thickness.

Grades

The 13 basic grades are as follows:

Electrical insulation grade: Primarily intended for electrical applications and others involving difficult bending or forming operations. It is sometimes referred to as "fishpaper."

Commercial grade: Considered to be the general-purpose grade, sometimes referred to as "mechanical and electrical grade." It possesses good physical and electrical properties and fabricates well.

Bone grade: Characterized by greater hardness and stiffness associated with higher specific gravity. It machines smoother with less tendency to separate the plies in the machining operations.

Trunk and case grade: Conforms to the mechanical requirements of "commercial grade," but has better bending qualities and smoother surface.

Flexible grade: Made sufficiently soft by incorporating a plasticizer, it is suitable for gaskets, packings, and similar applications. It is not recommended for electrical use.

Abrasive grade: Designed as the supporting base for abrasive grit for both disk and drum sanders. It has exceptional tear resistance, ply adhesion, resilience, and toughness.

White tag grade: It has smooth clean surfaces and can be printed or written on without danger of ink feathering.

Bobbin grade: Used for the manufacture of textile bobbin heads. It punches well under proper conditions, but is firm enough to resist denting in use. It machines to a very smooth surface.

Railroad grade: Used as railroad track joint, switch rods, and other insulating applications for track circuits.

Hermetic grade: Used as electric-motor insulation in hermetically sealed refrigeration units. High purity at low methanol extractables are essential because it is immersed in the refrigerant.

White grade: Recommended for applications where whiteness and cleanliness are essential requirements.

Shuttle grade: Design for gluing to wood shuttles to withstand the repeated pounding received in textile power looms.

Pattern grade: Made to provide maximum dimensional stability and minimum warp for use as patterns in cutting cloth, leather, and similar materials.

Vulcanized Oils

Vegetable oils vulcanized with sulfur and used for compounding with rubber for rubber goods, or as a rubber substitute. Castor oil, corn oil, rapeseed oil, and soybean oil are used. Tokenized oil is a white to brown, spongy, odorless cake, or a sticky plastic, with a specific gravity of 1.04. The material was invented in France in 1847 and was known as **factice**.

Factice cake is solidified, vulcanized oils, cut in slab form. It is an oil modifier of rubber, to add softness and plasticity. It also has some elasticity. **White factice** is made from rapeseed oil, which is high in a characteristic acid, crucic acid, by slow addition of sulfur chloride up to 25% sulfur content. **Erasing rubbers** are rubber compound with white factice or the factice alone. **Black factice** has mineral bitumen added to brown factice. **Factice sheet** is specially processed factice made by treating warm oil with sulfur and then with sulfur chloride. The strength and elasticity are higher. **Mineral rubber** was a name applied to vulcanized oils mixed with bitumens, especially gilsonite.

V-X Diagram

A graph of the isothermal or isobaric phase relationships in a binary system, the coordinates of the graph being specific volume and concentration.

Vycor

See *glass*.

Wafer

A slice of a semiconductor crystalline ingot. See also the term *slices*.

Wake Hackle

A *hackle* line extending from a singularity at the crack front in the direction of cracking. Such markings are associated with inclusions in ceramics and glasses—pores, bubbles, and solid particles—and are useful in determining the direction of crack propagation.

Walking-Beam Furnace

A continuous-type heat treating or sintering furnace consisting of two sets of rails, one stationary and the other movable, that lift and advance parts inside the hearth. With this system, the moving rails lift the work from the stationary rails, move it forward, and then lower it back onto the stationary rails. The moving rails then return to the starting position and repeat the process to advance the parts again.

Wallner Line (Ceramics and Glasses)

A fracture surface marking, having a wavelike profile in the fracture surface. Such marks frequently appear as a series of curved lines, indicating the direction of propagation of the fracture from the concave to the convex side of a given Wallner line. Also known as *ripple mark*.

Wallner Lines (Metals)

A distinct pattern of intersecting sets of parallel lines, sometimes reducing a set of V-shaped lines, sometimes observed when viewing brittle fracture surfaces at high magnification in an electron microscope. Wallner lines are attributed to interaction between a shock wave and a brittle crack front propagating at high velocity. Sometimes, Wallner lines are misinterpreted as fatigue striations. See the term *fatigue striations* (metals).

Wandering Sequence

Same as *random sequence*.

Warm Hardening

The term is occasionally used as an alternative to warm working and more usually refers to precipitation hardening at elevated temperature.

Warm Work

Deformation at a temperature above ambient but below that at which recrystallization occurs. The purpose may be to avoid some brittle

range, to benefit from the lower yield strength at higher temperature, or to minimize scaling. It induces work hardening similar to cold working and unlike hot working.

Warm Working

Deformation of metals at elevated temperature below the recrystallization temperature. The flow stress and rate of strain hardening are reduced within increasing temperature; therefore, lower forces are required than in cold working. See also *cold working* and *hot working*.

Warm-Setting Adhesive

Same as *intermediate-temperature-setting adhesive*.

Warp

A significant variation from the original true, or plane, surface or shape.

Warp (Composites)

The yarn running lengthwise in a woven fabric. A group of yarns in long lengths and approximately parallel. Also, in laminates, a change in dimension of a cured laminate from its original molded shape.

Warpage

Dimensional distortion in a plastic object.

Warpage (Metals)

(1) Deformation other than contraction that develops in a casting between solidification and room temperature. (2) The distortion that occurs during annealing, stress relieving, and high-temperature service.

Wash

(1) A coating applied to the face of a mold prior to casting. (2) An imperfection at a cast surface similar to a *cut*.

Wash Metal

Molten metal used to wash out a furnace, ladle, or other container.

Wash Primers

Wash primers are a special group of corrosion-inhibited coatings designed for use on clean metal surfaces. They are also known as “wash-coat primers,” “metal conditioners,” and “etch primers.”

W

The most widely utilized primers consist of a two-part system that is prepared at the point of use by simple mixing of specified proportions. The base grind portion contains a corrosion-inhibiting pigment, basic zinc chromate (also known as zinc tetroxy chromate), and a small amount of talc extender ground in an alcohol solution of polyvinyl butyral resin. The reducer portion consists of phosphoric acid, alcohol, and water. When these are mixed, a slow chemical reaction ensues, resulting in partial reduction of the chromate pigment. The life of the mixed primer is usually 9–12 h. Single-package primers are now in use.

Wastage

Loss of section by general corrosion, erosion, or abrasion.

Watch

A watch is a portable timepiece. Its operation may be described as mechanical, electromechanical, or electronic.

Mechanical and Electromechanical Watches

In the mechanical watch, a mainspring in the barrel stores operating energy; the user retightens the spring daily by means of the winding stem. The wheel train advances at five increments per second under control by the escapement. From there, the dial train turns the minute and hour hands across the watch face. The momentarily engageable setting feature enables the user to position the hands in accordance with a primary clock. The wheel train of four pairs, with an overall turns ratio of 1:40,000, reduces the high torque from the barrel to a low value controllable by the escapement, yet sufficient to drive the dial train.

Among the variety of features incorporated into modern watches or self-winding mechanism, substitution of an electrochemical cell for the mechanical mainspring, several forms of electromechanical escapement in place of the balance-and-hairspring mechanism, and instead of hands over a dial, marked disks viewed through windows for readout, extended to days of the week in calendar watches.

A significant improvement in accuracy of the electromechanical watch is provided by relocation of the time base mechanism from the output of the wheel train to the input. Instead of deriving power from a mainspring, this arrangement obtains power from a dry cell. In place of an escapement at the end of the wheel train to control its incremental advance, a tuning fork as a resonant element in an electronic oscillator reciprocates an index finger that rapidly ratchets against a fine-toothed index wheel at the input to the wheel train to initiate its advance. Through these actions, the tuning fork with its drive circuit serves both as time base and as electrical-to-mechanical transducer, introducing power from the dry cell into the wheel train as an intermediate level of torque. In one style of this watch, the tuning fork vibrates at 360 Hz; in a smaller style, the fork resonates at 480 Hz.

Electronic Watches

When solid-state electronic integrated circuits became available in quantity from production stimulated by digital computers, the all-electronic watch became a commercial reality. And in it, a chain of binary dividers triggered from a crystal oscillator develops a train of second pulses. These pulses drive a digital counter or scaler, which develops minute and hour pulses to activate the digital display. An externally switched fast/slow capacitor in the crystal oscillator

enables the user to set the readout in accordance with a standard time signal. The frequency of the crystal oscillator, typically in the tens of kilohertz, is chosen so that successive divisions by 2 produces desired 1 s pulse rate. For example, an oscillator with a 65.536 kHz crystal is followed by 16 binary dividers.

Power may be supplied by mercury or silver oxide cells, which are replaced annually, or lithium batteries, which operate for up to 5 years. To extend operating life, a solar cell may charge a nickel–cadmium power cell while the watch is illuminated.

One form of readout uses a light-emitting diode (LED). An assembly of these on a monolithic chip illuminates appropriate bars of a seven-segment display for each digit of the readout. The LED display itself illuminating and can be read in the dark. Because illumination of the readout consumes most of the power in an electronic watch, a liquid crystal display (LCD) is used where low-power consumption is a first consideration. The LCD readout depends for its indication on ambient illumination; the display is brighter in incident light. In it, glass plates confine a thin layer of liquid crystal. On the inside surface of the front plate, a transparent metallic coating in the seven-segment pattern receives signals from the readout counter. A highly reflective metal coating on the inside surface of the back plate operates at ground potential. When a bipolar high-frequency pulse train energizes a segment, the electric field established through the liquid causes that region to become turbulent and thereby scatter incident light so that the segment appears diffusely illuminated against a specularly illuminated background.

Water

Water is a chemical compound with two atoms of hydrogen and one atom of oxygen in each of its molecules. It is formed by the direct reaction:

of hydrogen with oxygen. The other compound of hydrogen and oxygen, hydrogen peroxide, really decomposes to form water, reaction:

Water is also formed in the combustion of hydrogen-containing compounds, in the pyrolysis of hydrates, and in animal metabolism.

Gaseous State

Water vapor consists of water molecules that move nearly independently of each other. The atoms are held together in the molecule by chemical bonds, which are very polar—the hydrogen end of each bond is electrically positive relative to the oxygen. When two molecules near each other are suitably oriented, the positive hydrogen of one molecule attracts the negative oxygen of the other, and while in this orientation, the repulsion of the like charges is comparatively small. The net attraction is strong enough to hold molecules together in many circumstances and is called a hydrogen bond.

When heated above 1200°C, water vapor disassociates appreciably to form hydrogen atoms and hydroxyl free radicals, reaction:

These products recombine completely to form water when the temperature is lowered. Water vapor also undergoes most of the chemical reactions of liquid water and, at very high concentrations, even shows some of the unusual solvent properties of liquid water. At about 374°C, order vapor may be compressed to any density without liquefying, and at a density as high as 0.4 g/cm³, it can dissolve appreciable quantities of salt. These conditions of high temperature and pressure are found in efficient steam power plants.

Solid State

Ordinary ice consists of water molecules joined together by hydrogen bonds in a regular arrangement. This unusual feature is a result of the strong and directional hydrogen bonds taking precedence over all other intermolecular forces in determining the structure of the crystal. If the water molecules were rearranged to reduce the amount of empty space, their relative orientations would no longer be so well suited for hydrogen bonds. This rearrangement can be produced by compressing ice to pressures in excess of 14 MPa. Altogether, five different crystalline forms of solid water have been produced in this way, the form obtained depending upon the final pressure and temperature. They are all denser than water, and all revert to ordinary ice when the pressure is reduced.

Liquid State

The molecules in liquid water also are held together by hydrogen bonds. When ice melts, many of the hydrogen bonds are broken and those that remain are not numerous enough to keep the molecules in a regular arrangement. Many of the unusual properties of liquid water may be understood in terms of the hydrogen bonds that remain. As water is heated from 0°C, it contracts until 4°C is reached and then begins the expansion that is normally associated with increasing temperature. This phenomenon and the increase in density when ice melts both result from a breaking down of the open, hydrogen-bonded structure as the temperature is raised. The viscosity of water decreases 10-fold as the temperature is raised from 0°C to 100°C, and this is also associated with the decrease of icelike character of the water as hydrogen bonds are disrupted by increasing thermal agitation. Even at 100°C, the hydrogen bonds influence the properties of water strongly, for it has a high boiling point and a high heat of vaporization compared with other substances of similar molecular weight.

Properties

Pure water, either solid or liquid, is blue if viewed through a thickness of more than 2 m. The other colors often observed are due to impurities.

Water is an excellent solvent for many substances, but particularly for those that disassociate to form ions. Its principal scientific and industrial use as a solvent is to furnish a medium for purifying such substances and for carrying out reactions between them.

Among the substances that dissolve in water with little or no ionization and that are very soluble are ethanol and ammonia. These are examples of molecules that are able to form hydrogen bonds with water molecules, although, except for the hydrogen of the OH group in ethanol, it is the hydrogen of the water that makes the hydrogen bond. On the other hand, substances that cannot interact strongly with water, either by ionization or by hydrogen bonding, or only sparingly soluble in it. Examples of such substances are benzene, mercury, and phosphorus.

Water is not a strong oxidizing agent, although it may advance the oxidizing action of other oxidizing agents, notably oxygen. Examples are the oxidizing action of water itself or its reactions with the alkali and the alkaline earth metals, even in the cold.

Water is an even poorer reducing agent than oxidizing agent. One of the few substances that it reduces rapidly is fluorine.

Water reacts with a variety of substances to form solid compounds in which the water molecule is intact, but in which it becomes a part of the structure of the solid. Such compounds are called hydrates and are formed frequently with the evolution of considerable amounts of heat.

Water Absorption

The ratio of the weight of water absorbent by a material to the weight of the dry material.

Water Atomization

See *atomization* (powder metallurgy).

Water Break

The appearance of discontinuous film of water on a surface signifying nonuniform wetting and usually associated with a surface contamination.

Water Break Test

A test to determine whether a surface is chemically clean by the use of a drop of water, preferably distilled water. If the surfaces are clean, the water will break and spread; a contaminated surface will cause the water to bead.

Water Drip Test

See *drip test*.

Water Droplet Erosion

Erosion by water droplets usually entrained in a high-velocity stream of air or steam. Also see *steam erosion* as this term is also used in reference to a particular case of water droplet erosion.

Water Quenching

A quench in which water is the quenching medium. The major disadvantage of water quenching is its poor efficiency at the beginning or hot stage of the quenching process. See also *quenching*.

Water Repellants

Chemicals used for treating textiles, leather, and paper such as washable wallpaper, to make them resistant to wetting by water. They are different from waterproofing materials in that they are used where it is not desirable to make the material completely waterproof but to permit the leather or fabric to "breathe." Water repellents must not form acids that would destroy the material, and they must set the dyes rather than cause them to bleed on washing. There are two basic types: a durable type that resists cleaning and a renewable type that must be replaced after the fabric is dry-cleaned.

W

Zelan, a pyridinium-resin compound of DuPont, is representative of the first type. *Quilon*, of the same company, is used for paper, textiles, and glass fabric and forms a strong chemical bond with the surface of the material by an attachment of the chromium end of the molecule through the covalent bond to the negatively charged surface. It is a stearotychromic chloride. The second type is usually an emulsion of a mineral salt over which a wax emulsion is placed; the treatment may be a one-bath process or may be by two separate treatments. *Aluminum acetate* is one of the most common materials for this purpose. Basic aluminum acetate is a white, amorphous powder. It is only slightly soluble in water but is soluble in mineral acids. *Niaproof* is a concentrated aluminum acetate water-proofing textile, and *Romssit* and *Migasol* are similar materials. Zirconium acetate, a white, crystalline material and its sodium salt are used as water repellants. *Zirconyl acetate*, a light-yellow solution containing 13% ZrO_2 , is used for both water repellancy and flame resistance of textile fibers. *Intumescent agents* are repellent coatings that swell and snuff out fire when they become hot. *Latex 744B*, a repellent of this type. It is the vinyl water emulsion compound that with pentaerythritol, dicyandiamide, and monosodium phosphate, is used in textiles, wallboard, and fiber tile.

Silicones have established their value as water-repellent finishes for a range of natural and synthetic textiles. The silicone polymers may be added as a solution, an emulsion, or by spraying a fine mist; alternatively, intermediates may be added that either polymerize in situ or attach themselves to the fibers. These techniques result in the pickup of 1%–3% of silicone resin on the cloth. Commercially, *di-chloromethylsilane* polymer is added as a solution or emulsion to a fabric; this is heated in the presence of a catalyst, such as zinc salt of an organic acid or an organotin compound, to condense the polymer to form a water-repellent sheath around each fiber. Fluorine-based polymers are also employed for treating fabrics. *Gore-Tex* is a polytetrafluoroethylene coating on nylon fabric; garments fashioned from this treated nylon are weatherproof and breathable. *Scotchgard*, from 3M, is a polymer containing fluoroalkyl groups that is effective for repelling both water and oil. *Scotchban*, from the same company, provides water, oil, and grease repellency to paper. Zepel B, from DuPont Co., is a fluoropolymer dispersion in water that does not promote yellowing or discoloration of coated outerwear. The *Quilon* series, also from DuPont, consists of greenish solutions of chrome complexes and iso-propanol that are water-repellant agents for packaging materials, nonwoven fabrics, and adhesive tapes. *Vinsol MM*, from Hercules, Inc., is a dark brown, free-flowing powder that is a sodium soap of a blend of Vinsol resin and a fatty acid. It was especially developed for use in masonry cements.

Water Side

The surface in contact with water, particularly a tube carrying water and heated on its exterior.

Water Side Corrosion

Severe corrosion on the water side of a tube. The term is commonly used in the context of externally fired steel tubes and steam-raising plants. Steel can develop a protective magnetite oxide on its surface when exposed to water of adequate purity but deviations from correct water conditions, for example, excessive oxygen, contamination with seawater or other chemicals can cause a severe attack, leading to large internal scabs, deep corrosion, and a form of hydrogen embrittlement.

Water Softeners

Chemical compounds used for converting soluble, scale-forming solids in water into insoluble forms. In the latter condition, they are then removed by setting or filtration. The hardness of water is due chiefly to the presence of carbonates, bicarbonates, and sulfates of calcium and magnesium; but many natural waters also contain other metal complexes that need special treatment for removal. Temporary *hard waters* are those that can be softened by boiling; permanent hard waters are those that require chemicals to change their condition. Sodium hydroxide is used to precipitate magnesium sulfate. Caustic lime is employed to precipitate bicarbonate of magnesium, and sodium aluminate is used as an accelerator. Barium carbonate may also be used. Prepared water softeners may consist of mixtures of lime, soda ash, and sodium aluminate, the three acting together. *Sodium aluminate* is a water-soluble, white powder melting at 1650°C, which is also used as a textile mordant, for sizing paper, and in making milky glass. Reynolds Metals Co. produces this material in flake form with iron content below 0.0056% for paint, water softeners, and paper coatings. Alum is used in settling tanks to precipitate mud, and zeolite is used extensively for filtering water. The liquids added to the washing water to produce fluffier textiles are *fabric softeners* and not water softeners. They are usually basic quaternary ammonium compounds such as distearyl dimethyl ammonium chloride with 16 and 18 carbon atoms, which are cationic, or positively charged. A thin coating is deposited on the negatively charged fabric, giving a lubricated cloth with a fluffy feel.

Water is also softened and purified with *ion-exchange agents*, which may be specially prepared synthetic resins. *Cation-exchange agents* substitute sodium for calcium and magnesium ions and produce soft waters. When the water is treated with a hydrogen derivative of a resin, the metal cations form acids from the salts. The carbonates are converted to carbonic acid that goes off in the air. When it is treated again with a basic resin derivative, or *anion-exchange agent*, the acids are removed. Water receiving this double treatment is equal to distilled water. Salt-cycle anion exchange substitutes chloride ions for other anions in the water, and when combined with cation exchange, it produces sodium chloride in the water in place of other ions.

BiQuist, from Purolite Ltd., is an anion-exchange resin developed at Oak Ridge National Laboratories to remove radioactive pertechnetate from groundwater. It can also be used to treat perchlorate anion in industrial discharge waters. Ion-exchange resins are also being used to remove metals from metal-plating and electronic wastewaters.

In electrolytic ion exchangers for converting seawater to freshwater, the basic cell is divided into three compartments by two membranes, one permeable only to cations and the other only to anions. The sodium ions migrate toward the cathode, and the chlorine ions go toward the anode, leaving freshwater in the center compartment. *Ion-exchange membranes* for electrodialysis (salt splitting or separation), and also used in fuel cells, are theoretically the same as powdered exchange resins but with an inorganic binder. Such a membrane resin of the Armour Research Foundation is made by the reaction of zirconyl chloride and phosphoric acid, giving a chain molecule of zirconium–oxygen with side chains of dihydrogen phosphate. *Zeolites* are crystalline aluminosilicates that display cation-exchange properties. The most common zeolite for softening uses is zeolite 4A, a sodium aluminosilicate made by Union Carbide Corp.

Water Tube Boiler

See *boiler tube*.

Water Wall

See *boiler tube*.

Water Wash (Thermal Spraying)

The forcing of exhaust air and fumes from a spray booth through water so that the vented air is free of thermally sprayed particles or fumes.

Water-Base Adhesives

A water-base adhesive formulation can be classified as a solution in which the polymer is totally soluble in water or alkaline water, or as a latex, which consists of a stable dispersion of polymer in an essentially aqueous medium. Solids content in water-base dispersions can be as high as 50% by volume. Many of the materials used in water-base adhesives are also used in organic-solvent-base adhesives. In recent years, exposure to organic solvents has been increasingly controlled by federal regulations. Therefore, it is advantageous to use water-base rather than organic-solvent-base adhesives. The use of water as a solvent results in lower-cost, nonflammability, and lower toxicity.

Water-base adhesives have fairly good resistance to organic solvents. However, moisture resistance is usually poor, and adhesives are subject to freezing, which can affect properties. Although there are many advantages to using water-base adhesives, there is still a large and important market for solvent-base adhesives. Water-base adhesives are usually unsuitable for hydrophobic surfaces, such as plastics, because of poor wettability. In addition, water shrinks some substances, such as paper, textiles, and, cellulose, and is corrosive to selected metals, such as copper. Organic-solvent-base adhesives are suitable for application on hydrophobic surfaces and are compatible with most metal surfaces.

Water-base adhesive solutions consist largely of natural adhesives. Materials that are soluble in water alone include animal glues, starch, dextran, methylcellulose, and polyvinyl alcohol. Materials that are soluble in alkaline water include casein, rosin, carboxymethylcellulose, shellac, vinyl acetate, and acrylate copolymers containing carboxyl groups. A water-base adhesive latex consists of a stable dispersion in an aqueous medium. Lattices can be classified as natural, synthetic, or artificial. A natural latex is formed from natural rubber. A synthetic latex is based on an aqueous dispersion of polymers obtained by emulsion polymerization. Adhesive families in this category include neoprene, styrene-butadiene rubber (SBR), nitrile rubber, polyvinyl acetate, polyacrylates, and polymethacrylates. An artificial latex is made simply by dispersing the solid polymer. Included in this category are natural rosin and its derivatives, synthetic butyl rubber, and reclaimed rubber.

Water-base adhesive families can be subdivided into materials used in making water-base adhesives only and materials used in making both water-base and organic-solvent-base adhesives. Included in the former classification are casein, dextran, starch, animal glues, polyvinyl alcohol, sodium carboxymethylcellulose, and sodium silicate. Included in the latter group are amino resins (urea and melamine formaldehydes), phenolic resins (phenol and resorcinol formaldehydes), polyacrylates, polyvinyl acetates, polyvinyl esters, neoprene, nitrile rubber, SBR, butyl rubber, natural rubber, and reclaimed rubber.

Water-base adhesive applications by demand include construction (15%), transportation (<1%), rigid bonding (<5%), packaging (60%), nonrigid bonding (<17%), consumer goods (<1%), and tapes (<3%). Rigid bonding applications for water-base adhesives include

appliances, housewares, machinery, and electronics. Nonrigid bonding applications include fabrics, shoes, filters, and rugs.

Water-Extended Polyester

A casting formulation in which water is suspended in the polyester resin.

Waterjet/Abrasive Waterjet Machining

A hydrodynamic machining process that uses AII for velocity stream of water as a cutting tool. This process is limited to the cutting of nonmetallic materials when the jetstream consists solely of water. However, when fine abrasive particles are injected into the water stream, the process can be used to cut harder and denser materials. Abrasive waterjet machining has expanded the range of fluid jet machining to include the cutting of metals, glass, ceramics, and composite materials. Water pressures up to 410 MPa are used. The coherent jet of water is propelled at speeds up to approximately 850 m/s.

Waterline Corrosion

Corrosive attack at the water to air interface of a partially submerged structure. It usually results from the highly oxygenated conditions in the area and hence is a form of differential aeration corrosion, but additional factors like wave action or marine organisms may be involved.

Water-Soluble Plastics

Within the plastics industry, water-soluble materials offer a variety of desirable physical properties yet retain the advantages inherent in a water system. These advantages include ease of handling, negligible solvent costs, low toxicity, and low flammability.

There is no sharp dividing line between water-dispersible and water-soluble polymers. Many so-called water-soluble plastics form colloidal dispersions rather than true solutions. In this text, emulsions or dispersions of water-insoluble polymers are not discussed (such as acrylics, polyvinyl acetate, styrene butadiene, and polyvinyl butyral).

The water-soluble plastics can be roughly divided into two general classes: thermoplastic resins and thermosetting resins.

Thermoplastic Resins

These plastics are usually synthesized by addition polymerization techniques. That is, small units (or monomers) are joined together to develop the final molecular weight and polymer configuration. Rarely do these polymers develop into long straight chains; considerable branching often occurs. The molecular weight chemistry of side groups and extent of branching all determine the properties that are obtained. These plastics are available as white or light-colored powders or in solution. Films, moldings, and extrusions are also available based on some of the thermoplastic resins.

Alkali-Soluble Polyvinyl Acetate Copolymers

Polyvinyl acetate itself is water insoluble. However, copolymers are available in which final acetate is copolymerized with an acidic comonomer. Such products retain the organic solubility of polyvinyl acetate but are soluble in aqueous alkali. These polymers exhibit low viscosity in solution and deposit high gloss films that are water

W

resistant, provided a volatile alkali such as ammonia is used. The use of a fixed alkali will result in a film with permanent water sensitivity. They generally possess good adhesion to cellulose and a wide variety of other surfaces.

Major uses include loom-finish warp sizes for dope dyed yarns, repulpable adhesives or sizes for paper and board, conditioning agents for masonry prior to painting, protective coatings for metals, and leveling agent and film former in self-polishing waxes.

Ethylene–Maleic Anhydride Copolymers

High-molecular-weight polymers have been prepared by copolymerizing ethylene and maleic anhydride. These resins are available either in “linear” form or cross-linked with either anhydride, free acid, or amide-ammonium salt side chains.

Major applications include general thickening and suspending in adhesives, agricultural chemicals, cleaning compounds, and ceramics. This resin is used as a thickener for latex and as a warp size for acetate filament.

Polyacrylates

Commercially important polymers are prepared by polymerizing either acrylic or methacrylic acid. Usually, these products are neutralized with bases to the salt form. Solution viscosity increases during neutralization. Cast films are hard, transparent, colorless, and somewhat brittle.

Polyacrylic acid itself is used as a warp size for nylon. The neutralized polymers (polyacrylates) are used in various coating and binding applications (ceramics, grinding wheels, etc.). Because of interesting solution properties, the polyacrylates are used as thickeners, flocculants, and sometimes as dispersants in applications such as ore processing, drilling muds, and oil recovery.

Polyethers

Two different polymer types are covered under this heading: polyoxyethylene (includes polyethylene glycols) and polyvinyl methyl ether and copolymers.

Polyoxyethylene (Polyethylene Glycol)

These resins are available over a wide molecular weight range. Low-molecular-weight members are slightly viscous liquids, whereas the medium-molecular-weight types (1,000–20,000) are waxy solids. Polymers up through this molecular weight level are known as polyethylene glycols. Extremely high-molecular-weight (several thousand to several million) homologues are also available. All types are soluble in water and in some organic solvents. Applications for the liquid and waxy solids include lubricants (rubber molds, textile fibers, and metal), bases for cosmetic and pharmaceutical preparations, and chemical intermediates for further reaction. The very high-molecular-weight types are useful principally as thickeners in many application areas.

Polyvinyl Methyl Ether

This unique family of vinyl polymers shows inverse solubility in that the resins precipitate out above 35°C. They do redissolve upon cooling, and the addition of low-molecular-weight alcohols increases the solubility in water and raises the precipitation temperature. Higher homologues are available that are water insoluble and quite tacky. The products exhibit pressure-sensitive adhesiveness coupled with good cohesive strength and high wet tack. Copolymers are available that contain maleic anhydride to modify physical properties, particularly solubility, or tolerance to water and organic solvents and ease of insolubilization. Major uses take advantage of properties such

as pressure-sensitive characteristics (adhesives), tackiness (various latex systems), thickening active, heat-sensitizing lattices for dip forming, and binding power (pigments).

Polyvinyl Alcohol

These resins are available commercially in a wide range of types, which vary in viscosity and chemical composition. Polyvinyl alcohol exhibits good water solubility, high resistance to organic solvents, oils, and greases, high tensile strength, adhesion, and flexibility. In addition, the polymer is resistant to oxidation and in film form is an excellent barrier for various gases. Certain types exhibit surface activity in solution and all types are soluble in both acid and alkaline media. The resins can be cross-linked by borax and numerous organic and inorganic agents to produce thickening or even insolubilization.

In adhesives, polyvinyl alcohol contributes machinability, viscosity control, specific adhesion, and in some cases remoistenability. Other major uses include paper coating and sizing (for increased strengths, ink hold-out, and grease resistance), textile sizing, wrinkle-resistant finishes (wash-and-wear fabrics in conjunction with thermosetting resins), polyvinyl acetate emulsion polymerization (protective colloid), binder (for nonwoven ribbons, filters, etc.), film (release agent in polyester and epoxy molding and water-soluble packaging), cement additive (for improved strength, toughness, and adhesion), and photosensitive coating (in the graphic arts industry).

Polyvinyl Pyrrolidone

Polyvinyl pyrrolidone (PVP) exhibits good solubility in both water and various organic solvents. A nontoxic material and tacky substance when wet, the polymer is a dispersant, suspending agent, and an adhesive component for bonding difficult surfaces.

Major uses include cosmetic preparations (hair sprays, etc.), tablet binding and coating, detoxifying of dyes, drug, and chemicals, beverage clarification, and specialty textile and paper applications involving sizing, dyeing, and printing.

Copolymers are also available (like PVP-vinyl acetate) that have some advantages over the homopolymers in heat sealability, pressure-sensitive adhesiveness, and other properties.

Polyacrylamide

These high-molecular-weight polymers are soluble in both cold and hot water and in selected organic solvents. The resin is an efficient thickener and by reaction can be changed in physical and chemical properties.

In addition to general uses for water-soluble resins, these resins have shown an outstanding ability to flocculate fines and increase the filtration rate of slurries. Consequently, polyacrylamide is used in ore processing and in other such systems where dispersed materials are encountered.

Styrene–Maleic Anhydride

Copolymers of these two monomers are soluble in some organic solvents and alkaline water. Styrene–maleic anhydride resins produce viscous and stable aqueous solutions. This resin is a strong polyelectrolyte. It is used as a textile warp size, paper coating, and static-electricity conductor. The polymer is also used in alkaline latex systems as a protective colloid, emulsifier, pigment dispersant, and filming aid.

Cellulosic Derivatives

Various commercial derivatives are prepared from alpha cellulose, which is obtained from several plant sources. One class of derivatives

is the water-soluble ethers. These products produce viscous aqueous solutions. All have some resistance to organic solvents, are hygroscopic, and are difficult to insolubilize.

Major industries that use these polymers as well as the water-soluble synthetic resins include food, pharmaceutical, cosmetic, textile, paper, petroleum (drilling muds), ceramic, paint, emulsion polymerization, and leather.

Hydroxyethylcellulose

This polymer is manufactured by reacting alkali cellulose with ethylene oxide. It can be water-soluble or only alkali-soluble depending on the extent of reaction. The alkali-soluble types possess the advantage of increased water resistance in deposited films. This polymer is somewhat intermediate in properties between methylcellulose and sodium carboxymethylcellulose. It is a protective colloid and relatively insensitive to the inclusion of multivalent ions in solution. The polymer is soluble in both hot and cold water, nonionic, but depolymerized by strong acids.

Water-soluble hydroxyethylcellulose is used in polyvinyl acetate emulsions as a stabilizer and in latex paints as a thickener and leveling agent.

Methylcellulose

Methylcellulose exhibits inverse water solubility in that it is more soluble at low temperatures than at high temperatures. It is nonionic in solution and is a very efficient thickener.

A major uses of latex paints (both polyvinyl acetate and acrylic types). Methylcellulose thickens the paint and contributes to good brushing characteristics as well. Other uses include bulking in laxatives and binding and thickening in cosmetics and pharmaceuticals.

Sodium Carboxymethylcellulose

This polymer is soluble in both hot and cold water. It exhibits good thickening action and suspending ability for particulates. Since solutions are ionic in character, they are somewhat sensitive to pH shifts and salt additions. Major uses include soil suspension in synthetic detergents and viscosity control in oil-well drilling muds.

Thermosetting Resins

A number of thermosetting resins are available in water solutions or in water-soluble form. These are principally the addition reaction products of formaldehyde with urea, phenolic, or melamine. Resorcinol and thiourea may also be reacted with formaldehyde to form water-soluble precondensates, although these have not attained the volume of the three main classes defined earlier.

These resins develop high molecular weight by a condensation reaction. The properties may change as the reaction proceeds. A-stage resins are those in which the degree of polymerization is minor. In some cases, the degree of polymerization of such that only dimers, trimers, or similar small units are prepared. These products are water soluble or at least can tolerate the addition of significant amounts of water.

Should the reaction proceed further, the polymers enter an area roughly defined as B-stage, in which they will tolerate addition of only small amounts of water but are soluble in certain organic solvents.

Manufacturers of thermosetting resins carry the polymerization reaction to the A- or B-stage. Further reaction (to the C-stage) is carried out by consumers of these resins.

As the condensation reaction proceeds and the molecular weight builds to form a rigid, three-dimensional system, the polymers

reach a point where they will not dissolve in organic solvents and are then termed *cured* (or C-staged). Further heating of the resin beyond this point may establish additional cross-links, but the physical properties do not change drastically. Once the resin has reached the C-stage, excessive heating leads to chemical breakdown of the material.

Thermosetting water-soluble polymers are treated with the and/or catalyst to advance the cure after deposition on a particular surface or within a particular structure. Thus, the water-solubility feature is important in that it allows easy manipulation without the cost and hazards of organic systems. However, water is an essential ingredient when cross-linking cellulose with low-molecular-weight thermosetting resins. The general characteristics of a fully cured, water-soluble, thermosetting resin are similar to those obtained by curing B-stage varnishes or molding compounds.

In many areas, the water-soluble thermosetting resins compete with one another. Certain ones may be preferred in an industry or in a certain particular application because of specific properties or cost. Generally, these resins offer high-temperature stability and hardness coupled with water and solvent resistance. Resistance to either acids or bases can also be obtained.

Cyclic Thermosetting Resins

In this category are cyclic ethylene urea-formaldehyde resins and triazones, which can be obtained by cyclization of dimethylolurea with a primary amine (usually ethylamine) and then adding 2 mol of formaldehyde. The cyclic thermosetting resins were developed principally for textile applications because they do not react or polymerize with themselves (as do other water-soluble thermosetting resins) but to react with the hydroxyls in cellulose through the methylol groups. These resins are called cellulose reactants and are by far the largest class of resins used in the wash-and-wear treatment of fabrics. Such resins impart crease resistance, wrinkle recovery, stiffness, tensile strength, water repellency, and good resistance to yellowing by chlorine-containing bleaches. In addition, there are increases in resiliency, dimensional stability, and permanent texturizing.

Cyclic ethylene urea-formaldehyde resins have the advantage over triazone in better color stability, absence of odor, and scorch resistance. Triazone resins have gained prominence particularly because they are more resistant to the effects of chlorine and are somewhat cheaper. Triazones are used principally to develop wash-and-wear properties on white cotton.

Melamine-Formaldehyde

In general, melamine-formaldehyde (MF) resins are the most expensive of the water-soluble thermosetting types. They possess good color, lack of odor, high abrasion resistance, and high resistance to alkali.

The major uses in decorating laminants for surfacing of wood, paper, and other products. Other uses include binding of rock wool and glass wool for thermal insulation, finishing of nylon for stiffness and resilience, and importing dimensional stability to wool and some cellulose.

Phenol-Formaldehyde

This very popular class of water-soluble thermosetting resins is intermediate in cost between the MF and the urea-formaldehyde (UF) types. They possess good water resistance, toughness, and acid resistance, although they are somewhat poorer than the MF resins in color, odor, and flame resistance. In most other physical and chemical properties, they are superior to the UF types.

W

Applications include laminates (including plywood and fabrics), grinding wheels, thermal insulation, battery separators, brake linings, and foundry uses.

Urea-Formaldehyde

These resins are the lowest cost as a class of the three general types but still cure to hard and somewhat brittle resins that have many desirable properties. The UF resins have an added plus in what they can cure at room temperature with suitable catalysts, whereas both the melamine-formaldehyde and phenol-formaldehyde types normally require temperatures in the neighborhood of 149°C to develop their full properties. The UF resins suffer somewhat in comparison with the other two types in poorer water resistance, less toughness, and poorer resistance to cyclical changes in temperature or water exposure.

UF resins are used in plywood because of ease of handling and lower temperature of cure, on paper for increased wet strength in air filters, and on certain rayon fabrics for improved stabilization and water resistance. The UF resins are used as insolubilizers for hydroxyl-containing polymers and in many of the general application areas for water-soluble, thermosetting resins.

Waterline Corrosion

Corrosive attack at the water to air interface of a partially submerged structure. It usually results from the highly oxygenated conditions in the area and hence is a form of differential aeration corrosion but additional factors like wave action or marine organisms may be involved.

Watt

A unit of electrical power equal to 1 J/s. Symbolized W.

Wave Number

The number of waves per unit length. Commonly used in infrared and Raman spectroscopy, the wave number is expressed as the reciprocal of the wavelength. The usual unit of wave number is the reciprocal centimeter (cm^{-1}).

Wave Soldering

An automatic soldering process where work parts (usually printed circuit boards) are automatically passed through a wave of molten solder. See also *dip soldering* and *soft soldering*.

Wavelength-Dispersive Spectroscopy (WDS)

A method of x-ray analysis that employs a crystal spectrometer to discriminate characteristic x-ray wavelengths. Compare with *energy-dispersive spectroscopy*.

Waviness

A wavelike variation from a perfect surface, generally much larger and wider than the roughness caused by tool or grinding marks. See the term *roughness*.

Wax

(1) Any of a group of substances resembling beeswax in appearance and character, and in general distinguished by their composition of

esters and higher alcohols, and by their freedom from fatty acids. (2) Preferred lubricant for pressing cemented carbide powder mixtures.

Wax

Wax is a general name for a variety of substances of animal and vegetable origin, which are fatty acids in combination with higher alcohols, instead of with glycerin as in fats and oils. They are usually harder than fats, less greasy, and more brittle, but when used alone to not mold as well. Chemically, the waxes differ from fats and oils in that they are composed of high-molecular-weight fatty acids with high-molecular-weight alcohols. The most familiar wax is beeswax from the honeybee, but commercial beeswax is usually greatly mixed or adulterated. Another animal wax is spermaceti from the sperm whale. Vegetable waxes include Japan wax, jojoba oil, candelilla, and carnauba wax.

Mineral waxes include paraffin wax from petroleum, ozokerite, ceresin, and montan wax. The mineral waxes differ from the true waxes and are mixtures of saturated hydrocarbons.

The animal and vegetable waxes are not plentiful materials and are often blended with or replaced by hydrocarbon waxes or waxy synthetic resins. However, waxes can be made from common oils and fats by splitting off the glycerin and re-esterifying selected mixtures of the fatty acids with higher alcohols.

Types and Uses

Some plastics have wax characteristics and may be used in polishes and coatings or for blending with waxes. Polyethylene waxes are light-colored, odorless solids of low molecular weight, of to about 6000. Mixed in solid waxes to the extent of 50%, and in liquid waxes up to 20%, they add gloss and durability and increase toughness. In emulsions, they add stability.

Waxes are employed in polishes, coatings, leather dressings, sizings, waterproofing for paper, candles, carbon paper, insulation, and varnishes. They are softer and have lower melting points than resins; they are soluble in mineral spirits and in alcohol and insoluble in water.

Synthetic waxes are used in liquid floor waxes, temporary corrosion protection, release agents, and as a melting point booster. There is a micronized polyethylene wax that is a processing and performance additive for adhesives, coatings, color concentrates, cosmetics, inks, lubricants, paints, plastics, and rubber. It can also be constituted from low-molecular-weight homopolymer, oxidized homopolymer, or as a copolymer. Another type is a methylene polymer used to blend with vegetable or paraffin waxes to increase the melting point, strength, and hardness. This is a mixture of terphenyls. It is a light-buff, waxy solid, highly soluble in benzene, and with good resistance to heat, acids, and alkalies. It is used to blend with natural waxes in candles, coatings, and insulation. Waxes are not digestible, and the so-called edible waxes used as water-resistant coatings for cheese, meats, and dried fruits are not waxes, but modified glycerides. One is a white, odorless, tasteless waxy solid melting at 40 °C, and is an acetylated monoglyceride of fatty acids.

Microcrystalline waxes are used for the vacuum impregnation of inorganic-filled, organic-bonded electrical insulation and coatings for ceramic capacitors and other electronic components. The wax is chosen because of its low moisture permeability.

Waxy emulsions have been widely used as binders for dry-press mixes and glaze suspensions. A high melting point paraffin also will make an excellent binder for dry-press granules. The paraffin is melted, added to the body, and then thoroughly incorporated by means of a heated muller-type mixer.

Ordinary paraffin also can be used to bond ceramic parts to steel plates for attachment to magnetic chucks during grinding.

Wax Pattern

A precise duplicate, allowing for shrinkage, of the casting and required gates, usually formed by pouring or injecting molten wax into a die or mold. See also *investment casting*.

Wax Pattern (Thermit Welding)

Wax molded around the parts to be welded to the form desired for the completed weld. See also the term *thermit welding*.

Wax Vent

A narrow passage through the core for a casting that allows venting of any gases formed in the core during the casting process. It is formed by incorporating in the core a string thickly coated with wax. When the core is baked, the wax evaporates or melts into the core and the string either burns or is pulled out to leave the passage.

Wear. (1) Damage to a solid surface, generally involving progressive loss of material, due to a relative motion between that surface and a contacting surface or substance. (2) The removal of material from a surface by frictional or other mechanical effects as it moves relative to another contacting surface. Two broad categories are recognized (see *abrasive wear* and adhesive wear and also *fatigue* and *pitting*. Compare with *surface damage*).

Wear Debris

Particles that become detached in a wear process.

Wear Pad

In forming, an expendable pad of rubber or rubberlike material of nominal thickness that is placed against the diaphragm to lessen the wear on it. See also *diaphragm* (3).

Wear Rate

The rate of material removal or dimensional change due to *wear* per unit of exposure parameter – for example, quantity of material removed (mass, volume, thickness) at unit distance of sliding or unit time.

Wear Rate (of Seals)

The amount of seal-surface wear, stated in terms of mils, worn in some designated time period. One commonly used unit is mils per hundred hours.

Wear Resistance

The resistance of a body to removal of material by the wear processes, expressed as the reciprocal of the wear rate. Wear resistance is a function of the conditions under which the wear process takes place. These conditions should always be carefully specified.

Wear-Resistant Steel

Many types of steel have wear-resistant properties, but the term usually refers to high-carbon, high-alloy steels used for dies, tooling, and parts subject to abrasion and for wear-resistant castings. They are generally cast and ground to shape. They are mostly sold under trade names for specific purposes. The excess carbon of the steels is in spheroidal form rather than as graphite. One of the earlier materials of this kind for drawing and forming dies is **Adamite**. It is a chromium-nickel-iron alloy with up to 1.5% chromium, nickel equal to half that of the chromium, and from 1.5% to 3.5% carbon with silicon from 0.5% to 2%.

The Brinell hardness ranges from 185 to 475 as cast, with tensile strengths up to 861 MPa. The softer grades can be machined and then hardened, but the hard grades are finished by grinding. Others have about 13% chromium, 1.5% carbon, 1.1% molybdenum, 0.70% cobalt, 0.55% silicon, 0.50% manganese, and 0.40% nickel. They are used for blanking dies, forming dies, and cams. T15 tool steel, for extreme abrasion resistance in cutting tools, is classed as a super high-speed steel. It is 13.5% tungsten, 4.5% chromium, 5% cobalt, 4.75% vanadium, 0.50% molybdenum, and 1.5% carbon. Its great hardness comes from the hard vanadium carbide and the complex tungsten-chromium carbides, and it has full red-hardness. The property of abrasion or wear resistance in steels generally comes from the hard carbides, and is thus inherent with proper heat treatment in many types of steel.

Wear Scar

The portion of a solid surface that exhibits evidence that material has been removed from it due to the influence of one or more wear processes.

Wear Transition

Any change in the wear rate or in the dominant wear process occurring at a solid surface. Wear transitions can be produced by an external change in the applied conditions (e.g., load, velocity, temperature, or gaseous environment) or by time-dependent changes (aging) of the materials and restraining fixtures in the *tribosystem*.

Weathering

Exposure of materials to the outdoor environment.

Weathering Steels

Copper-bearing *high-strength low-alloy steels* that exhibit high resistance to atmospheric corrosion in the unpainted condition.

Weave

The particular manner in which a fabric is formed by interlacing yarns and usually assigned a style number. See also the terms *basketweave* (composites), *crowfoot satin*, *eight-harness satin*, *leno weave*, and *plain weave*.

Weave Bead

A weld bead made with oscillation transverse to the axis of the weld. Contrast with *stringer bead*.

Weaving (of Weld)

The deposition of weld metal with significant side to side deflection of the arc or flame, together with any filler wire, relative to the main line of progress.

Web (Metals)

(1) A relatively flat, thin portion of a forging that affects an interconnection between ribs and bosses; a panel or wall that is generally parallel to the forging plane. See also *rib*. (2) For twist drills and reamers, the central portion of the tool body that joins the lands. (3) A plate or thin portion between stiffening ribs or flanges, as in an I-beam, H-beam, or other similar section.

Web (Plastics)

A thin plastic sheet in process in a machine. The molten web is that which issues from the die. The substrate web is the substrate being coated.

W

Webbing

Filaments or threads that sometimes form when adhesively bonded surfaces are separated. See also *legging* and *stringiness*. Compare with *teeth*.

Wedge Effect

The establishment of a pressure wedge in a lubricant. See also *wedge formation* (2).

Wedge Formation

(1) In sliding metals, the formation of a widge or wedges of plastically sheared metal in local regions of interaction between sliding surfaces. This type of wedge is known as a *prow*. It is similar to a *built-up edge*. (2) In hydrodynamic lubrication, the establishment of a pressure gradient in a fluid flowing into a converging channel. This is also known as *wedge effect*.

Weepage

A minute amount of liquid leakage by a seal. It is commonly considered to be a leakage rate of less than one drop of liquid per minute.

Weft

The transverse threads or fibers in a woven fabric. Those fibers running perpendicular to the warp. Also called *fill*, *filling yarn*, or *woof*.

Weight Percent

Percentage composition by weight. Contrast with *atomic percent*.

Weld

(1) A localized coalescence of metals or nonmetals produced either by heating the materials to suitable temperatures, with or without the application of pressure, or by the application of pressure alone and with or without the use of filler material. (2) A union formed between two components as a result of local mutual fusion or diffusion resulting from heating and, or, pressure. Where additional molten material is added to form or fill a joint the term "weld" is still used provided there is fusion of the main components and provided the melting point of the filler material is approximately similar to the melting point of the parent materials. Where the filler melting point is significantly lower, the terms soldering and brazing are appropriate. In these cases, there is no melting of the parent metals although there may be diffusion between the various components of the joint. Many welding processes are in use, see friction-, fusion-, arc-, gas-, GTA (TIG)-, GMA (MIG)-, welding etc.

Weldability

A specific or relative measure of the ability of a material to be welded under a given set of conditions. Implicit in this definition is the ability of the completed weldment to fulfill all functions for which support was designed.

Weldability Index

See *weld zone*.

Weldability Test

Any test for establishing whether a satisfactory joint can be produced by a particular welding procedure.

Weld Bead

The filler material deposited in a single pass of the welding arc or torch across a joint. It may also be termed a *run*.

Weldbonding

A joining method that combines resistance spot welding or resistance seam welding with adhesive bonding. The adhesive may be applied to a faying surface before welding or may be applied to the areas of sheet separation after welding.

Weld Brazing

A joining method that combines resistance welding with brazing.

Weld Crack

A crack in weld metal. See also *crater crack*, *root crack*, *toe crack*, and *underbead crack*.

Weld Cracking

Cracking that occurs in the weld metal. See also *cold cracking*, *hot cracking*, *lamellar tearing*, and *stress-relief cracking*.

Weld Decay

A form of intergranular corrosion and resultant cracking occurring in some austenitic stainless steels and certain nickel-based alloys that have been heated in the approximate temperature range 500–900 °C. This causes deposition of chromium carbides in the grain boundaries. The adjacent material is thereby depleted in chromium and consequently prone to corrosion in appropriate environments. Material in this condition is termed *sensitized*. The attack is a form of electrolytic corrosion (see *electrochemistry*) in which small anodic areas at the grain boundary are surrounded by large cathodic grains. Consequently, although the volume of material corroded may not be large, the rates of penetration and hence cracking can be very rapid. Most welding processes expose a narrowband of the heat-affected zone to the damaging temperature range so that weld decay can be observed as a line of cracking close to the edge of welds in susceptible steels. However, any heating in the appropriate temperature range can cause the same form of microstructural damage and the consequent attack may, perhaps confusingly, still be described as weld decay. Attack can be prevented by modification of the composition or other means, see *stabilized stainless steel*. No stress is necessary for corrosion of sensitized steel so the mechanism is not a form of stress corrosion. See the term *sensitization*.

Weld-Delay Time (Resistance Welding)

The amount of time the beginning of welding current is delayed with respect to the initiation of the forge-delay timer in order to synchronize the forging force with welding current flow.

Welder

A person making a weld. Colloquially, a machine for welding.

Weld Deposit

Fused weld metal comprising mainly filler but including some fused parent metal.

Weld Face

The exposed surface of the last metal to be deposited.

Weld Filler

Material added to a joint during welding. It is usually implicit that the filler is fused to become a load carrying component.

Weld Fusion Zone

Parent metal that has fused.

Weld Gage

A device for checking the shapes and sizes of welds.

Weld Heat Affected Zone

See *heat affected zone*.

Weld-Heat Time (Resistance Welding)

The time from the beginning of welding current to the beginning of post-heat time.

Welding

(1) Joining two or more pieces of material by applying heat or pressure, or both, with or without filler material, to produce a localized union through fusion or recrystallization across the interface. The thickness of the filler material is much greater than the capillary dimensions encountered in *brazing*. (2) May also be extended to include brazing and soldering. (3) In tribology, adhesion between solid surfaces in direct contact at any temperature.

Welding Alloys

Welding alloys are usually of the form of rod, wire, or powder used for either electric or gas welding, for building up surfaces, or for hardfacing surfaces. In the small sizes in continuous lengths, welding alloys are called welding wire. Nonferrous rods used for welding bronzes are usually referred to as brazing rods, as the metal to be welded is not fused when using them. Welding rods may be standard metals or special alloys, coated with a fluxing material or uncoated, and are normally in diameters from 0.239 to 0.635 cm. Compositions of standard welding rods follow the specifications of the American Welding Society. Molded carbon, in sizes from 0.318 to 2.54 cm in diameter, is also used for arc welding. Low-carbon steel rods for welding cast iron and steel contain less than 0.18% carbon. High-carbon rods produce a hard deposit that requires annealing, but these are used for producing a hard filler. High-carbon rods, with 0.85% to 1.10% carbon, will give deposits with an initial hardness of 575 Brinell, whereas high-manganese rod deposits will be below 200 Brinell but will work-harden to above 500 Brinell. For high-production automatic welding operations, carbon-steel wire may have a thin coating of copper to ease operation and prevent spattering. Stainless steel rods are marketed in various compositions. There are welding rods that comprise a range of stainless steels with either titania-lime or straight-lime coatings. Stainless C is an 18-8 type of stainless steel with 3.5% molybdenum. Aluminum-weld is a 5% silicon aluminum rod for welding silicon-aluminum alloys, and the Tungweld rods, for hard surfacing, are steel tubes containing fine particles of tungsten carbide. Kennametal KT-200 has a core of tungsten carbide and a sheathing of steel. It gives coatings with a hardness of Rockwell C63. Chromang, for welding high-alloy steels, is an 18-8 stainless steel modified with 2.5 to 4% manganese.

Welding rods with grades of high-manganese steel give hardnesses from 500 to 700 Brinell, and high-speed steel rods are used for facing worn cutting tools; others are used for facing surfaces requiring extreme hardness and have the alloy granules in a soft steel tube. The welded deposit has a composition of 30% chromium, 8% cobalt, 8% molybdenum, 5% tungsten, 0.05% boron, and 0.02% carbon.

There is a group of welding alloys made especially for welding machines. They are, in general, sintered tungsten or molybdenum carbides, combined with copper or silver, and are electrodes for spot welding rather than welding rods. Tungsten electrodes may be pure tungsten, thoriated tungsten, or zirconium tungsten, the latter two used for direct-current welding. Thoriated tungsten gives high arc stability, and the thoria increases the machinability of tungsten.

Zirconium tungsten provides adhesion between the solid electrode and the molten metal to give uniformity in the weld.

Thermit is a mixture of aluminum powder and iron oxide used for welding large sections of iron or steel or for filling large cavities. The process consists of the burning of the aluminum to react with the oxide, which frees the iron to molten form. To ignite the aluminum and start the reaction, a temperature of about 1538 °C is required, which is reached with the aid of a gas torch or ignition powder, and the exothermic temperature is about 2538 °C. Cast iron thermit, used for welding cast iron, is thermit with the addition of about 3% ferrosilicon and 20% steel punchings. Railroad thermit is thermit with additions of nickel, manganese, and steel.

The Stellite hardfacing rods are cobalt-based alloys that retain hardness at red heat and are very corrosion resistant. The grades have tensile strengths to 723 MPa and hardnesses to Rockwell C52. Inco-Weld Ais welding wire for stainless steels and for overlays. It contains 70% nickel, 16% chromium, 8% iron, 2% manganese, 3% titanium, and not more than 0.07% carbon. The annealed weld has a tensile strength of 551 MPa with elongation of 12%. Nickel welding rod is much used for cast iron, and the operation is brazing, with the base metal not melted. Nickel silver for brazing cast iron contains 46.5% copper, 43.4% zinc, 10% nickel, 0.10% silicon, and 0.02% phosphorous. The deposit matches the color of the iron. Colmonoy 23A is a nickel alloy welding powder for welding cast iron and filling blow holes in iron casting by torch application. It has a composition of 2.3% silicon, 1.25% boron, 0.10% carbon, not over 1.5% iron, and the balance nickel, with a melting point of 1066 °C. For welding on large structures where no heat treatment of the weldment is possible, the welding rods must have balanced compositions with no elements that form brittle compounds. Rockide rods are metal oxides for hard surfacing.

Welding Consumables

The materials used in producing a welded joint. The term includes fillers, electrodes, fluxes, etc., and possibly electricity and gases etc., but not parent material.

Welding Current (Automatic Arc Welding)

The current in the welding circuit during the making of a weld, but excluding upslope, downslope, start, and crater fill current.

Welding Current (Resistance Welding)

The current in the welding circuit during the making of a weld, but excluding preweld or postweld current.

Welding Cycle

The total series of activities and operations involved in a machine, or less commonly an operative, producing a single weld and returning to the start condition in the making of a weld.

Welding Electrode

See preferred term *electrode* (welding).

Welding Flux

Material applied to the weld zone primarily to chemically clean the surface, form a slag with impurities and prevent oxidation. Fluxes may contain components with other characteristics. See *electrode coating*.

W

Welding Force

See preferred terms *electrode force* and *platen force*.

Welding Generator

A generator used for supplying current for welding.

Welding Ground

Same as *work lead*.

Welding Head

The part of a welding machine or automatic welding equipment in which a welding gun or torch is incorporated.

Welding Leads

The electrical cables that serve as either *work lead* or *electrode lead* of an arc welding circuit.

Welding Machine

Equipment used to perform the welding operation. For example, spot welding machine, arc welding machine, seam welding machine, etc.

Weld (ing) Position

The orientation of components and weld deposits during the welding operation. A very wide range of terms and definitions have been used, often with some confusion. There are a limited number of positions by reference to the combination of weld slope and weld rotation. See horizontal-vertical, flat, vertical and overhead, these are the basic welding positions, and also inclined. Other authorities such as the American Welding Society Publications "Welding Terms and Symbols" offer alternative and more numerous definitions.

Welding Position

See also *flat position*, *horizontal position*, *horizontal fixed position*, *horizontal rolled position*, *inclined position*, *overhead position*, and *vertical position*.

Welding Pressure

The pressure exerted joins the welding operation on the parts being welded. See also *electrode force* and *platen force*.

Welding Primer

A painter or other coating applied to protect material until such time as it may be welded. It is implicit that the coating does not have any adverse effect on the weld and hence does not have to be removed prior to welding.

Welding Procedure

The detailed methods and practices, including joint preparation and welding procedures, involved in the production of a *weldment*.

Welding Process

A materials joining process that produces coalescence of materials by heating them to suitable temperatures, with or without the application of pressure or by the application of pressure alone, and with or without the use of filler metal.

Welding Rectifier

A device in a welding machine for converting alternating current to direct current.

Welding Rod

Material in the form of a rod that provides filler material. It may be bare solid rod, as used for most gas welding or coated rod or filled tube as used for most electric arc welding. See *electrode*. (2) It is used for welding or brazing which does not conduct the electrical current, and which may be either fed into the weld pool or preplaced in the joint.

Weld (ing) Sequence

The order in which a series of welding operations is performed. In particular, the order and direction in which a multi-run weld is deposited.

Welding Stress

Residual stress caused by localized heating and cooling during welding.

Welding Technique

The way in which the operative holds and moves the welding equipment, the electrode, or blowpipe, filler rod, etc., as they form the weld.

Welding Technology

Many terms are used in a specialized sense in welding. Those with a metallurgical aspect are included at their alphabetical location in this book. BS 499 "Welding Terms and Symbols" and American Welding Society Publication A.30-80 "Welding Terms and Symbols" detail many more terms of interest to the welding specialist.

Welding Tip

A welding torch tip designed for welding. See the term the *welding torch* (oxyfuel gas).

Welding Torch (Arc)

A device used in the gas tungsten and plasma arc welding processes to control the position of the electrode, to transfer current to the arc, and to direct the flow of shielding and plasma gas. See also *gas tungsten arc welding* and *plasma arc welding*.

Welding Torch (Oxyfuel Gas)

A device used in oxyfuel gas welding, torch brazing, and torch soldering for directing the heating flame produced by the controlled combustion of fuel gases. See also *oxyfuel gas welding*.

Welding Transformer

A transformer used for supplying current for welding.

Welding Voltage

See *arc voltage*.

Welding Wire

See preferred terms *electrode* and *welding rod*.

Weld Interface

The interface between weld metal and base metal in a fusion weld, between base metals in a solid-state weld without filler metal, or between filler metal and base metal in a solid-state weld with a filler metal and in a braze.

Weld Interval (Resistance Welding)

The total of all heat and cool time when making one multiple-impulse weld.

Weld-Interval Timer

A device used in resistance welding to control heat and cool times and weld interval when making multiple-impulse welds singly or simultaneously.

Weld Junction

The interface between weld metal and heat affected zone.

Weld Length

See preferred term *effective length of weld*.

Weld Line (Metals)

See preferred term *weld interface*.

Weld Line (Plastics)

The mark visible on a finished plastic part made by the meeting of two flow fronts of plastic material during molding. Also called weld mark, flow line, knit line, or stria.

Weldment

An assembly whose component parts are joined by welding.

Weld Metal

The portion of a weld that has been melted during welding or otherwise manipulated to form a joint.

Weld Metal Area

The area of the *weld metal* as measured on the cross section of a weld.

Weld Nugget

The weld metal in spot, seam, or projection welding. It is often termed the zone of fusion but little or none of the metal may have been above its melting point. See the terms *nugget* and *resistance spot welding*.

Weld Pass

A single progression of a welding or surfacing operation along a joint, weld deposit, or substrate. A single movement of the welding equipment moves across the component and which material is continuously fused. Also the material is fused or deposited in a single pass. The result of a pass is a weld bead, layer, or spray deposit.

Weld Penetration

See preferred terms *joint penetration* and *root penetration*.

Weld Prep (Aratation)

Generally, any activity associated with preparing an item for welding. More specifically the formation of the faces of a component to receive the weld deposit. For example, the edges of two plates to be welded together have a Vee preparation in which a single chamfer is formed on each edge.

Weld Procedure

The total prescribed system for performing a weld. It will define all significant variables such as materials, joint geometry, equipment set up, electrical and gas settings, preheat, interpass, and post-heating temperatures, etc.

Weld Root

Of a weld to be made, it is the area of the parent materials where the first deposit is to be made. Of a completed weld, it is the face of the first weld run that is remote from the operator.

Weld Rotation

The angle, relative to the vertical, of a line bisecting the angle between the fusion faces. Compare with *weld slope*.

Weld Run

Same as *weld pass*.

Weld Size

See preferred term *size of weld*.

Weld Slope

The angle, relative to the horizontal, of a line along the weld root. Compare with *weld rotation*.

Weld Tab

Additional material on which the weld may be initiated or terminated.

W

Weld Time (Automatic Arc Welding)

The time interval from the end of start time or end of upslope to beginning of crater fill time or beginning of downslope.

Weld Time (Resistance Welding)

The time that welding current is applied to the work in making a weld by single-impulse welding or flash welding.

Weld Timer

A device used in resistance welding to the weld time only.

Weld Voltage

See *arc voltage*.

Weld Zone

The neighborhood of a weld comprising all material involved in the weld operation including the weld deposit, the tip of any electrode or filler, and the adjacent parent metals. More generally, the area that may be affected by any aspect of welding such as oxidation, tarnishing, or spatter but not normally the larger area affected by residual welding stresses.

Steels to determine whether the numerous factors involved in each case collectively introduce a risk of cracking and whether the risk can be eliminated by preheating. Various procedures have been developed for determining weldability but one well-established system recognizes that the basic factors, for a non-preheated joint, are (i) the Hardenability of the steel, which is a function of composition, (ii) the Joint Severity, which is a function of the cross section of the parent material available to conduct heat from the joint, (iii) the amount of damaging hydrogen introduced into the weld zone, which is characteristic of the electrode coating (assuming no contamination), (iv) the heat input in terms of electrode size and burn off rate, and (v) the reduction in cooling rate resulting from preheating. The joint severity is assessed as a thermal severity number (TSN), which totals the number of 1/4 inch units of thickness available to conduct heat away, for example, a weld between two 1 inch thick plates would have a TSN of 8. The hardenability is determined from the composition in terms of the carbon equivalent (CE), for example, a steel with 0.2% carbon, 1% manganese, and 1% chromium would have a CE of 0.35. The CE is then allocated a Weldability Index (WI) letter depending upon the type of electrode coating to be used, for example, the CE of 0.35 would merit a Weldability Index of "E" with a Rutile coated electrode but "C" with a Low Hydrogen (Basic) coating. The TSN and WI are then compared with tables of various electrode sizes at the given burn off rates (in terms of length of electrode consumed per unit of weld deposit). For example, assuming that 1.5 inches of 10 gauge (0.128 inch diameter) electrode will be depositing 1 inch of weld metal then, with a TSN of 8 and a WI of "E," a preheat of about 200 °C is needed to reduce the cooling rate sufficiently to avoid cracking. Using a low hydrogen electrode and hence a WI of "C," reduces the necessary preheat to 125 °C and if, in addition, the electrode size is increased to 4 gauge (0.232 inch diameter) preheat is not necessary.

Wenstrom Mill

A rolling mill similar to a universal mill but where the edges and sides of the rolled section are acted on simultaneously.

Wet, Wettability

The property of a liquid, such as molten metal, to spread on a solid surface due to a low contact angle. This angle is a measure of the degree of wetting obtained in the solid-liquid system.

Wet-Bag Tooling

A rubber or plastic sheet mold used in cold isostatic or hydrostatic pressing of powders. See also *cold isostatic pressing*, *hydrostatic mold*, and *hydrostatic pressing*.

Wet Blasting

A process for cleaning or finishing by means of a slurry of abrasive in water directed at high velocity against the workpieces. Many different kinds and sizes of abrasives can be used in wet blasting. Sizes range from 20-mesh (very coarse) to 5000-mesh (which is much finer than face powder). Among the types of abrasives used are: organic or agricultural materials such as walnut shells and peach pits; novaculite, which is a soft type (6 to 6.5 Mohs hardness) of silica (99.46% silica); silica, quartz, garnet, and aluminum oxide; other refractory abrasives; and glass beads.

Wet Etching

Development of microstructure in metals with liquids, such as acids, bases, neutral solutions, or mixtures of solutions.

Wet Installation

A bolted joint in which a sealant is applied to the head and shank of the fastener such that after assembly a seal is provided between the fastener and the elements being joined. See also *sealant*.

Wet Lay-Up

A method of making reinforced plastics by applying the resin system as a liquid when the reinforcement is put in place. Polyesters and vinyl esters are the most commonly used family of resins used for wet lay-up.

Wet-Out

In composites fabrication, the condition of an impregnated *roving* or *yarn* in which substantially all voids between the sized strands and filaments are filled with resin.

Wet Strength (Adhesives)

The strength of an adhesive joint determined immediately after removal from a liquid in which it has been immersed under specified conditions of time, temperature, and pressure. The term is commonly used alone to designate strength after immersion in water. In latex adhesive, the term is used to describe the joint strength when the adherends are brought together with the adhesives still in the wet state. Compare with *dry strength* (adhesives).

Wet Strength (Composites)

The strength of an organic matrix composite when the matrix resin is saturated with absorbed moisture, or is at a defined percentage of absorbed moisture less than saturation (saturation is an equilibrium

condition in which the net rate of absorption under prescribed conditions falls essentially to zero).

Wetting

(1) The spreading and sometimes absorption of a fluid on or into a surface. (2) A condition in which the interface tension between a liquid and a solid is such that the contact angle is 0° to 90° . (3) The phenomenon whereby a liquid filler metal or flux spreads and adheres in a thin continuous layer on a solid base metal. (4) The formation of a relatively uniform, smooth, unbroken, and adherent film of solder to a basis metal. (5) This occurs when the attraction between the liquid and the surface exceeds the surface tension of the liquid. If the liquid tends to form discrete globules it is not wetting the surface and the angle formed between the two surfaces is a measure of wetting. An acute angle reflects poor wetting and an angle approaching 180° indicates good wetting.

Wetting Agent

(1) A substance that reduces the surface tension of a liquid, thereby causing it to spread more readily on a solid surface. (2) A surface-active agent that produces *wetting* by decreasing the *cohesion* within a liquid.

Wetting Agents

These are chemicals used in making solutions, emulsions, or compounded mixtures, such as paints, inks, cosmetics, starch pastes, oil emulsions, dentifrices, and detergents, to reduce the surface tension and give greater ease of mixing and stability to the solution. In the food industries, chemical wetting agents are added to the solutions for washing fruits and vegetables to produce a cleaner and bacteria-free product. Wetting agents are described in general as chemicals having a large hydrophilic group associated with a smaller hydrophobic group. Some liquids naturally wet pigments, oils, or waxes, but others require a proportion of a wetting agent to give mordant or wetting properties. Pine oil is a common wetting agent, but many are complex chemicals. They should be powerful enough not to be precipitated out of solutions in the form of salts, and they should be free of odor or any characteristic that would affect the solution. Aerosol wetting agents are in the form of liquids, waxy pellets, or free-flowing powders. There are other free-flowing powders, basically modified polyacrylates, that are soluble in water and less so in alcohol. There are sodium or ammonium dispersions of modified rosin, with 90% of the particles below $1\ \mu\text{m}$ in size. Also there is a sodium lignosulfonate produced from lignin waste liquor. It is used for dye and pigment dispersion, oil-well drilling mud, ore flotation, and boiler feed-water treatment.

Increasingly used by the ceramic industry is a popular type of poly-oxyethylene alkylate ether with a very high resistance to water hardness. Sulfonated types and carboxylates have moderate wetting properties and strong detergent and solubilizing tendencies.

Wet Winding

The process of *filament winding* of composites in which strands are impregnated with resin before or during winding onto the mandrel. See also *dry winding*.

Whale Oil

An oil extracted by boiling and steaming the blubber of several species of whale that are found chiefly in the cold waters of the extreme north and south. Whales are mammals and are predaceous, living

on animal food. The blubber blanket of fat protects the body, and the tissues and organs also contain deposits of fat. Most whale oil is true fat, namely, the glycerides of fatty acids, but the head contains a waxy fat. In the larger animals, the meat and bones yield more fat than the blubber. Both the whalebone whales and the toothed whales produce whale oil. The **bluehead whales** of the south are the largest and yield the most oil per weight. The whaling industry is under international control, and allocations are made on the basis of blue whale units averaging 20 tons (18 metric tons) of oil each. The **gray whale**, or **California whale**, of the northern Pacific, is a small 50-ft (15-m) species. The **Greenland whale** of the north, and the **finback whale** of the south, produce much oil. The **beluga**, or **white whale**, and the **narwhal**, of the north polar areas, produce **porpoise oil**. These species of porpoise measure up to 20 ft (6 m) in length.

Whale oil is sold according to grade, which depends upon its color and keeping qualities. The latter in turn depends largely upon proper cooking at extraction. Grades 0 and 1 are fine, pale-yellow oils, grade 2 is amber, grade 3 is a pale brown, and grade 4 has from 15% to 60% with a strong, fishy odor. The specific gravity is 0.920 to 0.927, saponification value is 180 to 197, and iodine value is 105 to 135. Whale oil contains oleic, stearic, palmitic, and other acids in varying amounts. But whales are now so scarce that the former uses of the oils and meat are restricted, particularly in the United States.

Whale oils of the lower grades have been used for quenching baths, heat-treating steels, and in lubricating oils. The best oils are used in soaps and candles, or for preparing textile fibers for spinning, or for treating leather. In Europe, whale oil is favored for making margarine because it requires less hydrogen than other oils for hardening, and the grouping of 16 to 22 carbon atom acids gives the hardened product greater plasticity over a wider temperature range. **Sod oil** is oil recovered from the treatment of leather in which whale or other marine mammal oil was used. It contains some of the tannins and nitrogenous matter, which makes it more emulsifiable and more penetrant than the original oil.

Whale meat was used for food in Japan and in dog food in the United States. When it is cured in air, the outside is hard and black, but the inside is soft. In young animals the flesh is pale, and in older animals it is dark red. It has a slight fishy flavor, but when cooked with vegetables is almost indistinguishable from beef. It contains 15 to 18% proteins. **Whale-meat extract** is used in bouillon cubes and dehydrated soups. It is 25% weaker than beef extract. **Whale liver oil** is used in medicine for its high vitamin A content. It also contains **kitol**, which has properties similar to vitamin A but is not absorbed in all animal metabolism. **Whalebones** are the elastic, hornlike strips in the upper jaw of the Greenland whale and some other species. Whalebone is lightweight, very flexible, elastic, tough, and durable. It consists of a conglomeration of hairy fibers covered with an enamel-like fibrous tissue. It is easily split and when softened in hot water is easily carved. Whalebone has a variety of uses in making whips, helmet frames, ribs, and brush fibers. **Balcen** is a trade name for strips of whalebone use for whips, and for products where great flexibility and elasticity are required.

Wheelabrator

A brand name of a machine for grit or shot blasting. In essence, it is a rotating wheel, which flings the shot from its periphery to impact the target component.

Wheelabrating

Deflashing molded plastic parts by bombarding them with small particles at high velocity. See also *flash* (plastics).

W

Whetstone

Stones of regular fine grains is composed largely of chalcedony silica, often with minute garnet and rutile crystals. They are used as fine abrasive stones for the final sharpening of edge tools. Whetstones are also sometimes selected, fine sandstones from the grindstone quarries. The finest Whetstones are called **oilstones**. A fine-grained **honestone**, known as **coticule**, comes from Belgium and is used for sharpening fine-edged tools. It is compact, yellow in color, and contains minute crystals of yellow manganese garnet, with also potash mica and tourmaline. Coticule is often cut double with blue-gray **phyllite** rock adhering to and supporting it. **Rubbing stones** are fine-grained Indiana sandstones.

Whirl (Oil)

(1) Instability of a rotating shaft associated with instability in the fluid film. (2) The deflection of a rotating shaft such that the axis of deflection works its way around the axis of rotation. Contrast with *catenary*.

Whisker

(1) A short single crystal fiber or filament used as a reinforcement in a matrix. Whisker diameters range from 1 to 25 μm , with *aspect ratios* generally between 50 and 150. (2) Single-crystal growths resembling fine wire, which may extend to 0.64 mm high. They most frequently occur on printed circuit boards or electronic components that have been electroplated with tin. (3) Metallic filamentary growths, often microscopic, sometimes formed during electrodeposition and sometimes spontaneously during storage or service, after finishing. (4) Fine, hair-like single crystal grown under controlled conditions and usually having only a single axial dislocation.

Whiskers are very fine single-crystal fibers that have length-to-diameter ratios of 50 to 10,000. Since they are single crystals, their strengths approach the calculated theoretical strengths of the materials. Alumina whiskers, which have received the most attention, have tensile strengths up to 0.2 million MPa and a modulus of elasticity of 0.5 million MPa. Other whisker materials are silicon carbide, silica nitride, magnesia, boron carbide, and beryllia.

Whiskers (Glass)

See striation (glass).

Whistlers

Narrow passages in a mold to allow the escape of pockets of entrapped air. The high velocity of the heated escaping air can cause a whistling noise.

White**Brass**

White brass is a bearing metal that is actually outside of the range of the brasses, bronzes, or babbitt metals. It is used in various grades; the specification is tin, 65%; zinc, 28% to 30%; and copper, 3% to 6%. It is used for automobile bearings, and is close-grained, hard, and tough. It also casts well. A different alloy is known under the name of white brass in the cheap jewelry and novelty trade. It has no tin, small proportions of copper, and the remainder zinc. It is a

high-zinc brass, and varies in color from silvery white to yellow, depending on the copper content.

White nickel brass is a grade of nickel silver. The white brass used for castings where a white color is desired may contain up to 30% nickel. The 60: 20: 20 alloy is used for white plaque castings for buildings. The high-nickel brasses do not cast well unless they also contain lead. Those with 15% to 20% nickel and 2% lead are used for casting hardware and valves. White nickel alloy is a copper-nickel alloy containing some aluminum. White copper is a name sometimes used for copper-nickel alloy or nickel brass. Nickel brasses known as German silver are copper-nickel-zinc white alloys used as a base metal for plated silverware, for springs and contacts in electrical equipment, and for corrosion-resistant parts. The alloys are graded according to the nickel content. Extra-white metal, the highest grade, contains 50% copper, 30% nickel, and 20% zinc. The lower grade, called fifths, for plated goods, has a yellowish color. It contains 57% copper, 7% nickel, and 36% zinc. All of the early German silvers contained up to 2% iron, which increased the strength, hardness, and whiteness, but is not desirable in the alloys used for electrical work. Some of the early English alloys also contained up to 2% tin, but tin embrittles alloys.

Cast Iron

White cast-iron solidifies with all its carbon in the combined state, mostly as iron carbide, Fe_3C (cementite). White iron contains no free graphite as does gray iron, malleable iron, and ductile iron. White iron derives its name from the fact that it shows a bright white fracture on a freshly broken surface.

The main use for white iron is as an intermediate product in the manufacture of malleable irons. In addition to this, white iron is made as an end product to serve specific applications that require a hard, abrasion-resistant material. White iron is very hard and resistant to wear, has a very high compressive strength, but has low resistance to impact, and is very difficult to machine.

By the proper balancing of chemical composition and section size, an iron casting can be made to solidify completely white throughout its entire section. By modifying the balance and adjusting the cooling rate, the casting can be made to solidify with a layer of white iron at the surface backed up by a core of gray iron. Castings with such a duplex structure are called "chilled iron" castings.

Castings of white iron and chilled iron find their main use in resistance to wear and abrasion. Typical applications include parts for crushers and grinders, grinding balls, coke and cinder chutes, shot-blasting nozzles and blades, parts for slurry pumps, car wheels, metalworking rolls, and grinding rolls.

White cast irons, which have alloy contents well above 4%, fall into three major groups:

1. Nickel-chromium white irons are low-chromium alloys containing 3% to 5% nickel and 1% to 4% chromium, with one alloy modification that contains 7% to 11% chromium. The nickel-chromium irons are also commonly identified as Ni-Hard types 1 to 4.
2. The high chromium irons contain 11% to 23% chromium, up to 3% molybdenum, and are often additionally alloyed with nickel or copper.
3. A third group comprises the 25% or 28% chromium white irons, which may contain other alloying additions of molybdenum and/or nickel up to 1.5%.

The high-alloy white irons are primarily used for abrasion-resistant applications and are readily cast into parts needed in machinery for

crushing, grinding, and handling of abrasive materials. The chromium content of high-alloy white irons also enhances their corrosion-resistant properties.

By using a fairly low silicon content, cast iron can be made to solidify white without the use of any additional alloy. Carbon contents are kept high (about 3.6%) when high hardness (575 Bhn) is desired. Such irons have very low toughness and a strength of about 240 MPa. For somewhat higher toughness and strength, at some sacrifice of hardness, the carbon content is lowered to about 2.8%. Unalloyed white and chilled irons have a structure composed of particles of mass of iron carbide in a matrix of fine pearlite. For highest hardness, strength, and toughness, the white iron is alloyed to produce a martensitic matrix surrounding particles of massive carbide.

Gold

White gold is the name of a class of jewelers' white alloys used as substitutes for platinum. The name gives no idea of the relative value of the different grades, which vary widely. Gold and platinum may be alloyed together to make a white gold, but the usual alloys consist of 20% to 50% nickel, with the balance gold. Nickel and zinc with gold may also be used for white golds. The best commercial grades of white gold are made by melting the gold with a white alloy prepared for this purpose. This alloy contains nickel, silver, palladium, and zinc. The 14-karat white gold contains 14 parts pure gold and 10 parts white alloy. A superior class of white gold is made of 90% gold and 10% palladium. High-strength white gold contains copper, nickel, and zinc with the gold. Such an alloy, containing 37.5% gold, 28% copper, 17.5% nickel, and 17% zinc, when aged by heat treatment, has a tensile strength of about 689 MPa and an elongation of 35%. It is used for making jewelry, has a fine, white color, and is easily worked into intricate shapes. White-gold solder is made in many grades containing up to 12% nickel, up to 15% zinc, with usually also copper and silver, and from 30% to 80% gold. The melting points of eight grades range from 695 to 845 °C.

Metals

Although a great variety of combinations can be made with numerous metals to produce white or silvery alloys, the name usually refers to the lead-antimony-tin alloys employed for machine bearings, packings, and linings, to the low-melting-point alloys used for toys, ornaments, and fusible metals, and to the type metals. Slush castings, for ornamental articles and hollow parts, are made in a wide variety of soft white alloys, usually varying proportions of lead, tin, zinc, and antimony, depending on cost and the accuracy and finish desired. These castings are made by pouring the molten metal into a metal mold without a core, and immediately pouring the metal out, so that a thin shell of the alloy solidifies against the metal of the mold and forms a hollow product. A number of white metals are specified by the American Society for Testing and Materials for bearing use. These vary in a wide range from 2% to 91% tin, 4.5% to 15% antimony, up to 90% lead, and up to 8% copper. The alloy containing 75% tin, 12% antimony, 10% lead, and 3% copper melts at 184 °C, is poured at about 375 °C, and has an ultimate compressive strength of 111 MPa and a Brinell hardness of 24. The alloy containing 10% tin, 15% antimony, and 75% lead melts at 240 °C, and has a compressive strength of 108 MPa and a Brinell hardness of 22. The first of these two alloys contains copper-tin crystals and the second contains tin-antimony crystals.

Society of Automotive Engineers (SAE) Alloy 18 is a cadmium-nickel alloy with also small amounts of silver, copper, tin, and zinc.

A bismuth-lead alloy containing 58% bismuth and 42% lead melts at 123.5 °C. It casts to exact size without shrinkage or expansion, and is used for master patterns and for sealing.

Various high-tin or reverse bronzes have been used as corrosion-resistant metals, especially before the advent of the chromium, nickel, and aluminum alloys for this purpose.

A white metal sheet now much used for making stamped and formed parts for costume jewelry and electronic parts is zinc with up to 1.5% copper and up to 0.5% titanium. The titanium with the copper prevents coarse-grain formation, raising the recrystallization temperature. The alloy weighs 22% less than copper, and it plates and solders easily.

White-Etching Layer

A surface layer in a steel that, as viewed in a section after etching, appears whiter than the base metal. The presence of the layer may be due to a number of causes, including plastic deformation induced by machining, or surface rubbing, heating during a metallographic preparation stage to such an extent that the layer is austenitized and then hardened during cooling, and diffusion of extraneous elements into the surface.

Whiteheart Malleable

See *malleable cast iron*.

White Layer

(1) Compound layer that forms in steels as a result of the *nitriding* process. (2) In tribology, a *white-etching layer*, typically associated with ferrous alloys, that is visible in metallographic cross sections of bearing surfaces. See also *Beilby layer* and *highly deformed layer*.

White Liquor

Cooking liquor from the kraft pulping process produced by recausticizing *green liquor* with lime. See also *kraft process*.

White Radiation

See *continuum*.

White Rust

Zinc oxide; the powder product of corrosion of zinc or zinc-coated surfaces.

Whiteware Ceramics

Technical whitewares include clays, porcelains, china, white stoneware, and steatites. The modern oxide ceramics would also be in this group. For technical use, these whitewares are usually vitrified (nonporous) or very nearly so. Most commonly, the pieces are glazed. To produce white-bodied ceramics, the raw materials must be of superior quality and selection.

Composition and Types

Most whiteware clays are basically kaolins and chemically hydrous aluminum silicates. Ball clays are less pure than kaolins and contain free silica and small amounts of other contaminants. Kaolins are generally not highly plastic, whereas ball clays are very plastic. The plasticity derives from the physical form of the minute particles, which are colloidal in size. Ball clays are not as white-burning as kaolins and impart color to the fired body.

W

Feldspars are used as fluxes to provide the alkaline oxides for the glassy phase surrounding the mullite ($3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$) crystals forming the mass of the body

Porcelains, China, and stoneware are composed of clays, silicate, and feldspar. Steatites are composed of talc (magnesium silicate) and clay. Minor variations are made to enhance special properties.

The porcelains, China, and stoneware are composed of alumina (Al_2O_3), silica (SiO_2), sodium and potassium oxides (Na_2O and K_2O), as well as calcia (CaO), zinc oxide (ZnO), zirconia (ZrO_2), titania (TiO_2), barium oxide (BaO), magnesia (MgO), and phosphoric oxide (P_2O_5). Some other oxides may be present as traces. Iron oxide is usually present in small amounts as an undesirable impurity.

The oxides are supplied in kaolin, ball clays, quartz, feldspar, whiting, magnesia, and talc. Oxide ceramics that do not use clays may use only mixtures of refined oxides.

Compounding and Forming

The raw materials are intimately mixed, usually by ball milling, and then prepared for forming into ware by use of the methods listed next. For jiggering and simple mechanical pressing or extruding, the ball-milled slip is dewatered, filter pressed, deaired, and extruded into convenient size billets.

For casting, the specific gravity is adjusted to give a good casting viscosity.

For dry pressing, the body is dried, shredded, and powdered or spray dried into minute granules.

The pieces are formed as close to size before firing as practical, allowing for the shrinkage during firing. This shrinkage may run as high as 25% and must be very closely controlled to avoid loss in the firing of off-dimension pieces.

The ware is formed in a number of ways, some of them unchanged for centuries or even thousands of years and others unknown 60 years ago. The following are the primary methods used:

1. Throwing or jiggering on mechanical potters wheel from plastic clay body
2. Casting in plaster of Paris mold from liquid slurry or slip
3. Pressing from plastic clay with simple mold
4. Pressing from dry powder in metal dies
5. Isostatic pressing from dry powder in rubber sack with hydraulic pressure
6. Hot pressing with heated clay blank and mold
7. Simple extrusion through die
8. Extrusion with thermoplastic resin to the body (injection molding)

Many pieces are formed by a combination of pressing or extrusion followed by mechanical shaping in lathes by special tools or dry grinding.

After forming, pieces are bisque fired, which drives out moisture and water of crystallization. Porcelain is not vitrified during the bisque firing. The porcelain bisque is dipped or sprayed with glaze and, in the second firing, the body and glaze mature or vitrify together.

China is vitrified in the first firing. In China manufacture, the glaze is applied to the fired body and the glaze matures in the second firing, which is at a lower temperature than the initial firing. In some cases, the glaze can be applied to an unfired piece and only one firing is needed.

Today, most kilns are fired with natural or manufactured gas, fuel oil, or electricity. The round beehive kiln fired periodically has been largely replaced with continuous tunnel kilns, which may be built with movable cars moving from one end to the other on a

straight track or as a circular tunnel with a moving floor. Periodic kilns are often used in specialized work where the volume does not justify use of a tunnel kiln. They are also more versatile.

The firing of technical ceramics is performed under the most carefully controlled conditions possible. Both the temperature and the atmosphere must be known and controlled. The ware must be properly placed in the kilns or damage to the piece will result. Warpage, uneven firing, and cracking can easily occur.

Maximum firing temperatures for unglazed refractory porcelain are usually about 1760°C . Laboratory chemical porcelain that is glazed is fired to 1454°C . Hotel, sanitary china, and electrical porcelain are usually fired about 1260°C . Steatite bodies mature at around 1260°C – 1316°C .

Wicking

(1) The flow of a liquid along a surface into a narrow space. This capillary action is caused by the attraction of the liquid molecules to each other and to the surface. (2) The flow of solder away from the desired area by *wetting* or *capillary action*.

Widmanstätten Structure

A structure characterized by a geometrical pattern resulting from the formation of a new phase along certain crystallographic planes of the parent solid solution. The orientation of the lattice in the new phase is related crystallographically to the orientation of the lattice in the parent phase. The structure was originally observed in meteorites but is readily produced in many alloys, such as titanium, by appropriate heat treatment. See the term *basketweave* (titanium).

Width

In the case of a beam, the shorter dimension perpendicular to the direction in which the load is applied.

Wildness

A condition that exists when molten metal, during cooling, evolves so much gas that it becomes violently agitated, forcibly ejecting metal from the mold or other container.

Williams Riser

An *atmospheric riser*.

Wind Angle

In filament winding of composites, the angular measure in degrees between the direction parallel to the filaments and an established reference. In filament-wound structures, it is the convention to measure the wind angle with reference to the centerline through the polar bosses, that is, the axis of rotation. See also *filament winding*.

Winding Pattern

In filament winding of composites, the total number of individual circuits required for a winding path to begin repeating by laying down immediately adjacent to the initial circuit. A regularly recurring pattern of the filament path after a certain number of mandrel revolutions, leading eventually to the complete coverage of the mandrel. See also *filament winding*.

Winding Tension

In filament winding or tape wrapping of composites, the amount of tension on the reinforcement as it makes contact with the mandrel. See also filament winding.

Window

A defect in thermoplastic film, sheet, or molding, caused by the incomplete plasticization of a piece of material during processing. It appears as a globule in an otherwise blended mass. See also *fish-eye* (plastics).

Winning

Recovering a metal from an ore or chemical compound using any suitable hydro-metallurgical, pyrometallurgical, or electrometallurgical method.

Wipe Etching

See *swabbing*.

Wiped Coat

A hot-dipped galvanized coating from which virtually all free zinc is removed by wiping prior to solidification, leaving only a thin zinc-iron alloy layer.

Wiped Joint

A joint made with solder having a wide melting range and with the heat supplied by the molten solder poured onto the joint. The solder is manipulated with a hand-held cloth or paddle so as to obtain the required size and contour. Traditionally, plumbers form soldered joints by wiping with a “moleskin.” See *solder*.

Wiper

A pad of felt or other material used to supply lubricant or to remove debris.

Wiper Forming, Wiping

Method of curving sheet metal sections or tubing over a form block or die in which this form block is moved relative to a wiper block or slide block.

Wire Flame Spraying

A thermal spraying process variation in which the material to be sprayed is in wire or rod form. See also *flame spraying*.

Wire Glass

A sheet glass used in building construction for windows, doors, floors, and skylights, having woven wire mesh embedded in the center of the plate. It does not splinter or fly apart as common glass when subjected to fire or shock, and it has higher strength than common glass. It is made in standard thicknesses from 0.125 to 0.375 in. (0.318–0.953 cm) and in plates 60 × 110 in. (1.5 × 2.8 m) and 61 × 140 in. (1.5 × 3.6 m). Wire glass is made from plain, rough, or polished surfaces, or with ribbed or cobweb surface on one side for diffusing the light and for decorative purposes. It is also obtainable

from corrugated sheets. Plastic-coated wire mesh may be used to replace wire glass for hothouses or skylights where less weight and fuller penetration of light rays are desired. *Cel-O-Glass*, of DuPont, is a plastic-coated wire mesh in sheet form.

Wire Rod

Hot-rolled coiled stock that is to be cold drawn into wire.

Wire Straightener

A device used for controlling the cast of coiled weld filler-metal wire to enable it to be easily fed into the welding gun.

Wiring

Formation of a curl along the edge of a shell, tube, or sheet and insertion of a rod or wire within the curl for stiffening the edge. See also curling.

Witness Mark

A surface mark revealing or confirming some action or process.

Wohler Fatigue Test

A fatigue test in which the specimen is a rotating cantilever, driven at the supported end and loaded via a bearing at the other. A rotation produces a single reversed stress cycle.

Wolfram

An old name for tungsten now usually referring to tungsten ores.

Wollaston Wire

Any wire made by the Wollaston process of fine-wire drawing. It consists of inserting a length of bare drawn wire into a close-fitting tube of another metal, the tube and core then being treated as a single rod and drawn through dies down to the required size. The outside jacket of metal is then dissolved away by an acid that does not affect the core metal. **Platinum wire** as fine as 0.00005 in. (0.00013 cm) in diameter is made commercially by this method, and gold wire as fine as 0.00001 in. (0.00002 cm) in diameter is also drawn. Wires of this fineness are employed only in instruments. They are marketed as composite wires, the user dissolving off the jacket. **Taylor process wire** is a very fine wire made by the process of drawing in a glass tube. The process is used chiefly for obtaining fine wire from a material lacking ductility, such as antimony, or extremely fine wire from a ductile metal. The procedure is to melt the metal or alloy into a glass or quartz tube and then draw down this tube with its contained material. Wire as fine as 0.00004 in. (0.00012 cm) in diameter has been made, but only in short lengths.

Wood

For most purposes, wood may be defined as the dense fibrous substance that makes up the greater part of a tree. It is found beneath the bark and in the roots, stems, and branches of trees and shrubs. Of the three sources, the stem or trunk furnishes the bulk of raw material for lumber products.

W

Wood is a renewable resource. It is grown just about everywhere and can be produced in any reasonable quantity needed for future consumption. Wood products and the management of forested lands are changing to meet modern conditions; hence, trees were grown to meet modern production requirements for size, quality, and quantity. For example, with the developments in the modern technique of gluing, the former use of extremely wide, thick, and excessively long lumber is no longer necessary. Laminated lumber and plywood have generally taken the place of these large boards and timbers. Not only are the raw materials for such products easier to grow and more economical to obtain that are solid timbers of comparable size, but also the products are generally improved by the use of modern methods of fabricating.

Although there are many species of wood, the commercially important types can be grouped into two categories of about 25 for each group.

Anatomy

Wood is composed mostly of hollow, elongated, spindle-shaped cells that are arranged parallel to each other along the trunk of a tree. The characteristics of these fibrous cells and their arrangement affect strength properties, appearance, resistance to penetration by water and chemicals, resistance to decay, and many other properties.

The combined concentric bands of light and dark areas constitute annual growth rings. The age of a tree may be determined by counting these rings at the stump.

In temperate climates, trees often produce distinct growth layers. These increments are called growth rings or annual rings when associated with yearly growth; many tropical trees, however, lack growth rings. These rings vary in width according to environmental conditions. Where there is a visible contrast within a single growth ring, the first-form layer is called earlywood and the remainder latewood. The earlywood cells are usually larger and the cell walls thinner than the latewood cells. With the naked eye or a hand lens, earlywood is shown to be generally lighter in color than latewood.

Because of the extreme structural variations in wood, there are many possibilities for selecting a species for a specific purpose. Some species (e.g., spruce) combine light weight and relatively high stiffness and bending strength. Very heavy woods (e.g., lignum vitae) are extremely hard and resistant to abrasion. A very light wood (such as balsa) has high thermal insulation value; hickory has extremely high short resistance; mahogany has excellent dimensional stability.

Many mechanical properties of wood, such as bending strength, crushing strength, and hardness, depend on the density of wood; the heavier woods are generally stronger. Wood density is determined largely by the relative thickness of the cell wall and the proportions of thick- and thin-walled cells present.

Hardwoods and Softwoods

The terminology used in the classification of trees is confusing, but because it has become general in usage, it is important for those who make or purchase products of wood to understand it.

The terms hardwood and softwood have no direct application to hardness or softness of the materials. Basswood is a softer domestic species, yet the yellow pines, which are classed as softwood, are often much harder. Even balsa, a foreign species that everyone knows, the lightest and the softest wood used in commerce, is classed as hardwood. For practical purposes, the hardwoods have broad leaves, whereas the softwoods have needlelike leaves. Trees (hardwoods) with broad leaves usually shed them at some time during the year, while the conifers (softwoods) retain a covering of the needlelike

foliage throughout the year. There are quite a few exceptions to these criteria; but as users gain familiarity with the various woods, they will soon learn by experience into which group a species falls.

Those who use wood must know something of the botanical classification because the lumber industry is also divided into two distinct groups. The methods of doing business and manufacturing and grading for quality differ from each other.

Generally, the hardwoods are used for the manufacture of factory-made products, such as tools, furniture, flooring, and instrument cases. The largest market for softwoods is in the home construction field or for other building purposes. But there is no line of demarcation that is reliable, for hardwoods and softwoods are often interchangeable in use.

The more important hardwoods are as follows:

Alder	Ash	Aspen	Basswood
Beech	Birch	Cherry	Chestnut
Cottonwood	Elm	Hackberry	Hickory and Pecan
Holly	Locust	Magnolia	Maple (hard and soft)
Oak	red Oak	White	Sweet or Red
Gum	Sycamore	Tupelo or Black Gum	Walnut black
Willow black	Yellow Popular		

The more important softwoods are the following:

Cedar (several species)	Cypress Douglas Fir (not a true fir)	Firs (eastern and western)
Hemlock (eastern and western)	Larch Pine	eastern white Pine
jack Pine	lodgepole Pine	pitch Pine
Ponderosa Pine	red Pine	southern yellow (several species) Pine
sugar Pine	Virginia Pine	western white Redwood
eastern Spruce	Englemann Spruce	Spruce Sitka Tamarack

Hardwood

The horizontal plane of a block of hardwood (e.g., oak or maple) corresponds to a minute portion of the top surface of a stump or end surface of a log. The vertical plane corresponds to a surface cut parallel to the radius and parallel to the wood rays. The vertical plane corresponds to a surface cut at right angles to the radius and the wood rays, or tangentially within the log. In hardwoods, these three major planes along which wood may be cut are known commonly as end-grain, quarter-sawed (edge-grain), and plain-sawed (flat-grain) surfaces.

Softwood

The rectangular units that make up the end grain of softwood are sections through long vertical cells called tracheids or fibers. Because softwoods do not contain vessel cells, the tracheids serve the dual function of transporting sap vertically and giving strength to the wood. Softwood fibers range from about 3 to 8 mm in length.

Cell Walls and Composition

The principal compound in mature wood cells is cellulose, a polysaccharide of repeating glucose molecules that may reach 4 μ m in length. The cellulose molecules are arranged in an orderly

manner into structures about 10–25 nm wide called microfibrils. This ordered arrangement in certain parts (micelles) gives the cell wall crystalline properties that can be observed in polarized light with a light microscope. The microfibrils wind together like strands in a cable to form macrofibrils that measure about 0.5 μm in width and may reach 4 μm in length. These cables are as strong as an equivalent thickness of steel.

Wood, regardless of the species, is composed of two principal materials: cellulose, which is about 70% of the volume, and lignin, nature's glue for holding the cells and fibers together, which is from 20% to 28%. Residues in the form of minerals, waxes, tannins, oils, etc., compose the remainder. The residues, although small in volume, often provide a species with unusual properties. The oils in cypress are responsible for it is renowned as a decay-resistant wood. Aromatic oils provide many of the cedars with distinctive odors that make them valuable for clothing storage chests. Other chemicals provide resistance to water absorption, which is useful for constructing light, high-speed boats that are relatively free from increase in weight due to water absorption.

Many of the chemical residues of wood can be removed by neutral solvents, such as water, alcohol, acetone, benzene, and ether. Some of them may be caused to migrate from one part of the wood to another.

Structure of Wood

The roots, stem, and branches of a tree increase in size by adding a new layer each year, just as the size of one's hand is increased by putting on a glove. The layer or growth ring will vary in thickness due to the age of the tree, growing conditions, amount of foliage, and other factors.

The growth ring is divided into two parts—spring wood and summer wood. The former is usually lighter in weight than the latter and is denser and stronger. Generally, a tree or portion of a tree with the most summer wood is stronger than one that has less.

The thickness of the growth ring and the relative amounts of spring and summer wood have a greater effect on the appearance of wood and are often a deciding factor in the choice of furniture materials. Excessively, thick growth rings usually provide a rather coarse-textured material, whereas narrow growth rings provide fine texture. However, in hardwoods, a thick ring usually does have more summer wood and is, therefore, the stronger of the two. The situation is somewhat different for the softwoods.

Grades of Lumber

Modern grading of lumber is the result of experience. Over a period of 90 years, there has been a gradual evolution to meet the changes in industry. This trend will continue as long as wood products are used.

The grading of hardwoods and softwoods is entirely different; the former are used almost entirely as raw materials for manufactured products. For these, basic grading is on the number of usable cuttings or pieces that can be cut from a board. For some grades, these cuttings need only be sound, but for others they must be clear at least on one face. The cuttings must also be of a certain size.

Hardwood Grading

The grades of hardwood lumber from the highest quality to the lowest are "Firsts," the top-quality grade; the next are known as "Seconds." These two grades are usually marketed as one and called "Firsts and Seconds"; the designation for the grade is FAS. The next lowest grade is "Selects," followed by "No. 1 Common," "No. 2

Common," "No. 3A Common," and "No. 3B Common." Sometimes, a grading is further differentiated, such as "FAS One Face," which means that it is of a much higher grade on one face than on the other. A prefix "WHND" is also used sometimes. It means that wormholes are not to be considered as defects in evaluating cuttings nor as a reason for disqualifying them as might otherwise be done.

Softwood Grading

The theory of softwood lumber grading is probably somewhat more difficult for the layperson to understand than that used for the hardwoods. This is because many of the species are graded under separate association rulings, which are similar, but with some important differences.

Furthermore, softwoods are divided into three general classes of products, each of which is graded under a different set of rules.

1. *Yard lumber*, which is used for building construction and other ordinary uses, is unobtainable in "Finish Grades," which are called "A," "B," "C," "D"; "Common Boards," which are called "No. 1," "No. 2," "No. 3," "No. 4," and sometimes "No. 5"; and as "Common Dimension" in grades "No. 1," "No. 2," and "No. 3."
2. *Structural lumber* is a relatively modern concept in the field of lumber grading. It is an engineered product intended for use where definite strength requirements are specified. The allowable stresses designated for a piece of structural lumber depend upon the size, number, and placement of the defects. The relative position of a defect is of great importance; therefore, if the maximum strength of the piece is to be developed, it must be used in its entirety. It cannot be remanufactured for width, thickness, or length.
3. *Factory and shop lumber* is the third general category. These grades are similar to those for hardwoods in that the lumber is graded by the number of usable cuttings that can be taken from a board, but here the resemblance ceases, for both the grade descriptions and nomenclature, are different. The term "Factory and Shop" is descriptive of the uses for which the product is designed. Much of it is used for general millwork products, patterns, models, etc., and wherever it is necessary to cut up softwood lumber for the production of factory-made items.

Wood Chemicals

These are chemicals obtained from wood. The practice was carried out in the past and continues wherever technical utility and economic conditions have combined to make it feasible. Woody plants comprise the greatest part of the organic materials produced by photosynthesis on a renewable basis and were the precursors of the fossil coal deposits. Future shortages of the fossil hydrocarbons from which most organic chemicals are derived may be the result of the economic feasibility of the production of these chemicals from wood.

Wood is a mixture of three natural polymers—cellulose, hemicelluloses, and lignin—and an approximate abundance of 50:25:25. In addition to these polymeric cell wall components, which make up the major portion of the wood, different species contain varying amounts and kinds of extraneous materials called extractives. Cellulose is a long-chain polymer of glucose that is embedded in an amorphous matrix of the hemicelluloses and lignin. Hemicelluloses are shorter or branched polymer of five- and six-carbon sugars other than glucose. Lignin is a three-dimensional polymer formed

W

of phenol–propane units. Thus, the nature of the chemicals derived from wood depends on the wood component involved.

Modern Processes

Chemicals derived from wood at present include bark products, cellulose, cellulose esters, cellulose ethers, charcoal, dimethyl sulfoxide, ethyl alcohol, fatty acids, furfural, hemicellulose extracts, kraft lignin, lignin sulfonates, pine oil, rayons, rosin, sugars, tall oil, turpentine, and vanillin.

Most of these are either direct products or by-products of wood pulping, in which the lignin that cements the wood fibers together and stiffens them is dissolved away from the cellulose. High-purity chemical cellulose or dissolving pulp is the starting material for such polymeric cellulose derivatives as viscous rayon and cellophane (regenerated celluloses from the xanthate derivative in fiber or film form), cellulose esters such as the acetate and butyrate for fiber, film, and molding applications, and cellulose ethers such as carboxymethylcellulose, ethylcellulose, and hydroxy-ethylcellulose for use as gums.

Potential Chemicals

Considerable development effort has been devoted to the conversion of renewable biomass, of which wood is the major component, into the chemicals usually derived from petroleum. Processes for which technical feasibility has been demonstrated and economic feasibility is influenced by fossil hydrocarbon cost and availability.

Wood Degradation

This refers to decay of the components of wood. Despite its highly integrated matrix of cellulose, hemicellulose, and lignin, which gives the wood superior strength properties and a marked resistance to chemical and microbial attack, a variety of organisms and processes are capable of degrading wood. The decay process is a continuum, often involving a number of organisms over many years. Wood degrading agents are both biotic and abiotic, and include heat, strong acids and bases, organic chemicals, mechanical wear, and sunlight (ultraviolet degradation).

Engineering Design

This is the process of creating products, components, and structural systems with wood and wood-based materials. Wood engineering design applies concepts of engineering in the design of systems and products that must carry loads and perform in a safe and serviceable fashion. Common examples include structural systems such as buildings or electric power transmission structures, components such as trusses or prefabricated stressed-skin panels, and products such as furniture or pallets and containers. The design process considers the shape, size, physical and mechanical properties of the materials, type and size of the connections, and the type of system response needed to resist both stationary and moving (dynamic) loads, and function satisfactorily in the end-use environment.

Wood is used in both light frame and heavy timber structures. Light frame structures consist of many relatively small wood elements such as lumber covered with a sheathing material such as plywood. The lumber and sheathing are connected to act together as a system in resisting loads; an example is a residential house wood floor system where the plywood is nailed to lumber bending members or joists. In this system, no one joint is heavily loaded because the sheathing spreads the load out over many joists. Service factors such as deflection or vibration often govern the design of floor systems rather than strength.

Light frame systems are often designed as diaphragms or shear walls to resist lateral forces resulting from wind or earthquake.

In heavy timber construction, such as bridges or industrial buildings, there was less reliance on system action and, in general, large beams or columns carry more load transmitted through decking or panel assemblies. Strength, rather than deflection, often governs the selection of member size and connections. There are many variants of wood construction using poles, wood shells, folded plates, prefabricated panels, logs, and combinations with other materials.

Engineered Wood Composites

Wood composites are products composed of wood elements that have been glued together to make a different, more useful or more economical product than solid sawn wood. Plywood is a common example of a wood composite sheathing panel product where layers of veneer are glued together. Plywood is used as a sheathing material in light frame wood buildings, wood pallets, and containers to distribute the applied forces to beams of lumber or other materials. Shear strength, bending strength, and stiffness are the most important properties for these applications and may be engineered into the panel by adjusting the species and quality of veneer used in the manufacture.

Processing

Processing involves peeling, slicing, sawing, and chemically altering hardwoods and softwoods to form finished products such as boards or veneer; particles or chips for making paper, particle, or fiber products; and fuel.

Most logs are converted to boards in a sawmill that consists of a large circular or band saw, a carriage that holds the log and moves past the saw, and small circular saws that remove excess bark and defects from the edges and ends of the boards. One method is to saw the log to boards with a single pass through several saw blades mounted on a single shaft (a gang saw). Sometimes, the outside of the log is converted to boards or chips until a rectangular center or cant remains. The cant is then processed to boards with a gang saw.

Other steps taken may be drying or machining, including veneer cutting. Wood is also ground to fibers for hardboard, medium-density fiberboard, and paper products. It is sliced and flaked for particle-board products, including wafer boards and oriented strand boards. Whether made from waste products (sawdust, planer shavings, slabs, edgings), or roundwood, the individual particles generally exhibit the anisotropy and hygroscopicity of larger pieces of wood. The negative effects of these properties are minimized to the degree that the three wood directions (longitudinal, tangential, and radial) are distributed more or less randomly.

Wood Products

Wood products are those products, such as veneer, plywood, laminate of products, particle-board, waferboard, pulp and paper, hardboard, and fiberboard, made from the stems and branches of coniferous (softwood) and deciduous (hardwood) tree species. The living portion of the tree is the region closest to the bark as commonly referred to as sapwood; the dead portion of the tree is called heartwood. In many species, especially hardwoods, the heartwood changes color because of chemical changes in it. The heartwood of walnut, for example, is dark brown and the sapwood almost white.

Wood is one of the strongest natural materials for its weight. A microscopic view reveals thousands of hollow-tubed fibers held together with a chemical called lignin. These hollow-tubed fibers

give wood its tremendous strength for its light weight. These fibers, after the lignin bonding material is removed, make paper. In addition to lignin, wood is composed of other chemicals, including cellulose and hemicellulose. This category includes lumber products, veneer, and structural plywood.

Lumber

Most small log sawmills try to maximize value and yield by automating as much of the manufacturing process as possible. The basic process of cutting lumber involves producing as many rectangular pieces of lumber as possible from a round tapered log. There are only a few sawing solutions, out of millions possible, that will yield the most lumber from any given log or larger timber.

Veneer and Structural Plywood

Structural plywood is constructed from individual sheets of veneer, often with the grain of the veneer in perpendicular directions in alternating plies. The most common construction is three-, four-, and five-ply panels. The alternating plies give superior strength and dimensional stability.

Composite Products

These include laminated products made from lumber, particleboard, waferboard, and oriented strand board.

Laminated Products

Laminated products are composite products, made from lumber, parallel laminated veneer, and sometimes plywood, particleboard, or other fiber product. The most common types are the laminated beam products composed of individual pieces of lumber glued together with a phenyl resorcinol-type adhesive. Laminated beams are constructed by placing high-quality straight-grained pieces of lumber on the top and bottom, where tension and compression stresses are the greatest, and lower-quality lumber in the center section, where the stresses are lower.

Another form of composite beam is constructed from individual members made from parallel laminated veneer lumber. This type of lumber has the advantage that it can be made into any length, thus creating beams to span large sections. These beams can be made entirely of parallel laminated veneer lumber, or with the top and bottom flange made from parallel laminated veneer lumber, and the center web made from plywood or flakeboard. Some of these products use solid lumber for the flange material and resemble an I beam. All structural laminated products have the advantage over lumber in that much of the natural variation due to defects is removed, and wood structural members can be made much larger than the typical 51 × 305 mm lumber product.

Particleboard

Nonstructural particleboard is another type of composite product that is usually made from sawdust or planer shavings. It is sometimes made from flaked roundwood. This type of particleboard is one of the most widely used forms of wood product. Often hidden from view, it is used as a substrate under hardwood veneer or plastic laminates. It is commonly used in furniture, cabinets, shelving, and paneling. Particleboard is made by drying, screening, and sorting the sawdust and planer shavings into different size classifications.

Waferboard and Oriented Strand Board

Waferboard and oriented strand board are structural panels made from flakes or strands and are usually created from very small trees. Unlike nonstructural particleboard, waferboard is designed for use in

applications similar to those of plywood. Waferboard and oriented strand board can have flakes or strands oriented in the same direction, thus giving the board greater strength in the long axis. The most common type of waferboard is made from randomly oriented flakes.

Fiber Products

The most common fiber products result from pulping processes that involve the chemical modification of wood chips, sawdust, and planer shavings. Such products include pulp and paper, hardboard, and fiberboard.

Pulp and Paper

Paper making begins with the pulping process. Pulp is made from wood chips created in the lumber manufacturing process, small roundwood that is chipped, and recycled paper. The fibers in the chips must be separated from each other by mechanically grinding the fibers or chemically dissolving the lignin from them. The most common chemical processes are sulfite and sulfate (kraft). Following the pulping process, the fibers are washed to remove pulping chemicals or impurities. In some processes (e.g., writing papers), the fibers are bleached.

Dry, finished paper emerges from the end of this section, and it is placed in rolls for further manufacture into paper products.

Hardboard

Hardboard is a medium- to high-density wood fiber product made in sheets from 1.6 to 12.7 mm. Hardboard is used in furniture, cabinets, garage door panels, vinyl overlaid wall panels, and pegboard. It is made by either a wet or dry process.

Medium-Density Fiberboard

Medium-density fiberboard is used in many of the same applications where particleboard is used. It can be used in siding and is especially well suited to cabinet and door panels where edges are exposed. Unlike particleboard, which has a rough edge, medium-density fiberboard has a very fine edge that can be molded very well. Medium-density fiberboard is produced in much the same way that dry-processed hardboard is produced in its early stages. The chips are thermomechanically pulped or refined prior to forming into a dry mat. Following refining, medium-density fiberboard is produced in a fashion similar to that of particleboard. The dried pulp is sprayed with adhesive (usually urea-formaldehyde or phenol-formaldehyde) and formed into a dry mat prior to pressing in a multiopening hot press. After the panels have been formed, they are cooled and cut to smaller final product sizes prior to shipment.

Other Engineered Wood Products

The list of processes and potential processes that are available for wood construction is almost endless. The laminating of wood can be extended to using species of one kind for the surfaces and another for the core. Also, other species having altogether different properties may be used in other places of the assembly. Decking for aircraft carriers is a good example; the surface of the decking must have high abrasion resistance, but great strength in bending is also required. The combination of several species in the same timber is, therefore, most effective.

Barrels and other cylindrical containers are made of laminated wood staves, plywood, or veneer. Hogsheads for tobacco export are of solid staves or plywood.

W

Wood can be treated to provide considerable fire resistance; it then can be destroyed by heat but will not support combustion.

Natural wood is not adversely affected by extremes of cold such as are encountered in high latitudes and is, therefore, much in use for shelters, tools, sporting equipment, and other products where these conditions exist.

Wood is widely used for structures and products that must be nonmagnetic; hence, it is used for minesweepers and similar craft. Laminated wood has no peer for this type of product.

Special treatments have been developed for use in power-line construction. These treatment materials must act as nonconductors as well as preservatives.

Wood has excellent thermal insulating properties. It is used for refrigerated spaces, refrigerated delivery trucks, and in a great many other places where light weight and thermal insulation, combined with strength, are necessary. For example, specially treated milk containers are in widespread use in the dairy industry.

Special forms of timbers are manufactured for boxcar decking. Decking of this type provides a medium for fastening cargo as well as furnishing other needed functions.

In the textile industry, wood, both treated and in the natural form, is used for shuttles and bobbins, pulleys, and many other types of machinery.

Wood, in a natural form, treated or laminated, is used for water and other liquid conduits, cooling towers, and chemical containers.

Preservation/Protection

There are several wood preservation methods. The system used depends upon the service requirements. For example, a railroad tie, once in place, must withstand continuous exposure to the elements and almost every conceivable condition that promotes decay, until it is worn out some 20–30 years later. It is, therefore, necessary to provide this and similar items with maximum protection.

The two general methods of treating are surface applications where the wood is exposed to the chemicals by dipping, soaking, or brushing, and the treatments wherein the chemicals are forced into the wood through pressure. These latter treatments are used for the most critical applications. Pressure-treating operations must be conducted in plants with considerable equipment. It is a specialized business, and a large industry has arisen to take care of the many needs for highly treated products.

The most effective way to prevent damage through exposure of untreated wood is to perform all major machining operations prior to treating. If this is impossible, the exposed parts should be given a surface treatment by brushing or dipping. Unfortunately, neither of these treatments is as effective as the original pressure treating. All domestic species can be pressure-treated, but some of them require it less than others. The inherently decay-resistant species, such as cypress, redwood, some of the cedars, and white oak, need no treatment for most uses. But this applies only to the heartwood of any specie.

Of the various chemicals used for wood preservative treatment, with the pressure system, creosote is one of the oldest and best. However, it has an odor that is sometimes offensive and is, therefore, not generally suitable for manufactured items that may be used in contact with the body, or adjacent to food or enclosed places where the fumes may become objectionable. It can also be somewhat of a fire hazard and is sometimes not used for this reason. A third objection to creosote is the difficulty of painting over it. However, creosote is very effective against decay fungi and insect damage.

There are several effective forms of copper salts. These can be painted over; they do not contribute to fire hazard and are odorless.

They are extensively used in the manufacture of boats and other marine appliances.

A relatively new chemical for decay and insect prevention is pentachlorophenol. This has most of the advantages of creosote, except that it is probably not as effective against termite damage and is more expensive, but it lacks most of the disadvantages and can be used in enclosed places.

For food containers, preservative treatments are not generally recommended unless the conditions are closely examined and there is assurance that the chemicals are approved under the existing laws and are in no way harmful to health.

The second method of treatment is by one of the surface systems. Generally, the chemicals used for this purpose are almost the same as for pressure treating. However, they are often specially prepared and their carriers may differ to obtain greater natural penetration.

Of the various methods of application, dipping is the most efficient, for in this way all of the surface is exposed to the chemicals and a maximum amount of usable chemical is deposited, which may not be the case with brush or spray treatments. Often, heating the chemicals and cooling the pieces during dipping will increase penetration. However, long periods of soaking are not usually of much advantage. It is better to dip the wood parts for several minutes (sufficient time to assure that surface exposure is complete) and then pile the pieces closely together soon after they are removed from the chemical bath. Several days of natural absorption under these conditions will often provide a surprising amount of penetration. The success of this method depends to a considerable extent on the type of chemical used and particularly the carrier.

In the millwork industry, the surface method of application is of tremendous importance and is widely used for nearly all its products. Windows, storm sash, exterior trim, and most other products exposed to weather are effectively treated. In addition, the preservative chemicals are often combined with waxes or oils to provide a reasonable amount of dimensional stability.

Properties

The physical and mechanical characteristics of wood are controlled by specific anatomy, moisture content, and, to a lesser extent, mineral and extractive content. The properties are also influenced by the directional nature of wood, which results in markedly different properties in the longitudinal, tangential, and radial directions or axes. Wood properties within a species vary greatly from tree to tree and within a single axis. The physical properties (other than appearance) are moisture content, shrinkage, density, permeability, and thermal and electrical properties.

The mechanical properties of wood include elastic, strength, and vibration characteristics. These properties are dependent upon species, grain orientation, moisture content, loading rate, and size and location of natural characteristics such as knots.

Because wood is an orthotropic material, it has unique and independent mechanical properties in each of three mutually perpendicular axes—longitudinal, radial, and tangential. This orthotropic nature of wood is interrupted by naturally occurring characteristics such as knots that, depending on size and location, can decrease the stiffness and strength of the wood.

Wood Failure

The rupturing of wood fibers in strength tests on adhesively bonded specimens, usually expressed as the percentage of the total area involved that shows such failure.

Wood Flour

A pulverized wood product used in the foundry to furnish a reducing atmosphere in the mold, help overcome sand expansion, increase flowability, improve casting finish, and provide easier shakeout.

Finely ground dried wood employed as a filler and as reinforcing material in molding plastics and in linoleum, and as an absorbent for nitroglycerin. It is made largely from white-colored softwoods, chiefly pine and spruce, but maple and ash flours are preferred where no resin content is desired. Woods containing essential oils, such as cedar, are not suitable. Wood flour is produced from sawdust and shavings by grinding in burr mills. It has the appearance of wheat flour. The sizes commonly used are 40, 60, and 80 mesh; the finest is 140 mesh. Grade 1, used as a filler in rubber and plastics, has a particle size of 60 mesh and a specific gravity of 1.25, but 80 and 100 mesh are also used for plastics filler. Since wood flour absorbs the resin or gums when mixed in molding plastics and sets hard, it is sometimes mixed with mineral powders to vary the hardness and toughness of the molded product.

These quantities of *sawdust* are obtained in the sawmill areas. Besides being used as a fuel, it is employed for packing, for finishing metal parts in tumbling machines, for making particleboard, and for distilling to obtain resins, alcohols, sugars, and other chemicals. Some sawdust is pulped, and as much as 20% of such pulp can be used in kraft paper without loss of strength. Hickory, walnut, and oak sawdusts are used for meat smoking, or for the making of *liquid smoke*, which is produced by burning the sawdust and absorbing the smoke into water. For the rapid production of bacon and other meats, immersion in liquid smoke imitates the flavor of smoked meat. Some sawdust is used for agricultural mulch and fertilizer by chemical treatment to accelerate decay. *Bark fuel* is shredded bark, flash-dried and palletized with powdered coal. *Particleboard*, made by compressing sawdust or wood particles with a resin binder into sheets, has uniform strength in all directions, and a smooth, grainless surface. When used as a core for veneer panels, it requires no cross-laminating. Mechanical pulp for newsprint can be made from sawdust, but the quantity available is usually not sufficient. The material known as *ground wood*, of fine-mesh fibers, is made from cord wood, about 1 ton of fibers being produced from one cord of pulpwood. *Plastic wood*, usually marketed as a paste in tubes for filling cavities or seams in wood products, is wood flour or wood cellulose compounded with a synthetic resin of high molecular weight that will give good adhesion but not penetrate the wood particles to destroy their nature. The solvent is kept low to reduce shrinkage. When cured in place, the material can be machined, polished, and painted.

Wood Laminate

See *built-up laminated wood*, *glue-laminated wood*, and *plywood*.

Wood Preservatives

These fall into two general classes: oils, such as *creosote* and petroleum solutions of *pentachlorophenol*; and *waterborne salts* that are applied as water solutions. **Coal tar** creosote, a black or brownish oil made by distilling coal tar, is the oldest and still one of the more important and useful wood preservatives. Because it has recently been classified as a carcinogen, its use is expected to decrease. Its advantages are high toxicity to wood-destroying organisms; relative insolubility in water and low volatility, which impart to it a great degree of permanence under the most varied use conditions; ease of application; ease with which its depth of penetration can be determined; general availability and relatively low cost; and long record of satisfactory use.

Creosotes distilled from tars other than coal tar are used to some extent for wood preservation. For many years, either *cold tar* or *petroleum oil* has been mixed with cold tar creosote in various proportions to lower preservative costs.

Water-repellent solutions containing chlorinate phenols, principally pentachlorophenol, in solvents of the mineral spirit type have been used in commercial treatment of wood by the millwork industry since about 1931.

Pentachlorophenol solutions for wood preservation generally contain 5% (by weight) of this chemical, although solutions with volatile solvents may contain lower or higher concentrations. Preservative systems containing water-repellent components are sold under various trade names, principally for the dip or equivalent treatment of window sash and other millwork. According to federal specifications, the preservative chemicals may not contain less than 5% pentachlorophenol.

Standard wood preservatives used in water solution include *acid copper chromate*, *ammoniacal copper arsenite*, *chromated copper arsenate*, *zinc naphthenate*, *chromated zinc chloride*, and *fluor chrome arsenate phenol*. These preservatives are often employed when cleanliness and paintability of the treated wood are required. The chromated zinc chloride and fluor chromate arsenate phenol formulations resist leaching less than preservative oils and are seldom used where a high degree of protection is required for wood in ground contact or for other wet installations. Several formulations involving combinations of copper, chromium, and arsenic have shown high resistance to leaching and very good performance in service. The ammoniacal copper arsenite and chromated copper arsenate are included in specifications for such items as building foundations, building poles, utility poles, marine piling, and piling for land and freshwater use. *Organic sulfones* are another class of wood preservatives offering high degrees of protection. One such product is *diiodomethyl p-tolyl sulfone*, with trade name *Amical*.

Wood Veneer

A thin sheet of wood generally within the thickness range from 0.3 to 6.3 mm (0.01–0.25 in.) to be used in a laminate.

Woods, Imported

There are over 100 different species of foreign woods that are imported into the United States. By far, the greatest number of these are used for decorative or nonengineering purposes—some are used for both.

Imported woods to be considered here are all defined as imported species, except those that are also native to the United States. Thus, all Canadian kinds are excluded because the United States has every species of wood that grows in Canada. Mexico, on the other hand, supplies some tropical woods not found in the United States. These are pines from the highlands of Mexico and Central America that are imported in fairly sizable volume at times, but the engineering aspects of their utilization coincide directly with the southern pine found in the United States; consequently, no attempt is made to describe these. No other softwoods (conifers) are imported for uses as engineering materials. Thus, all types discussed here are categorized as hardwood (broadleaf) species. Even balsa is a hardwood because the terms “hardwood” and “softwood” in lumber-industry parlance allude to the botanical classification rather than the actual hardness or softness of the wood.

There are over 13 kinds of tropical hardwoods known to be used for engineering products or purposes. In certain parts of the world, there are vast expanses of untouched tropical forests, which, no doubt, contain several other hardwoods of potential

W

engineering value. However, the woods and current use are typical imported woods and applications:

1. Refrigeration: balsa
2. Wharves and docks: Greenheart, ekki, jarrah, ironbark, apitong, angelique
3. Boat construction: Philippines mahogany, Central and South American mahogany, African mahogany, balsa, apitong, teak, iroko, ironbark, jarrah, lignum vitae
4. Tanks and vats: Philippine mahogany, apitong
5. Building construction: mahogany (all types), apitong, balsa, greenheart
6. Poles, piling: greenheart, ekki
7. Machinery: lignum vitae
8. Aircraft and missiles: balsa
9. Vehicles: apitong

Wood-Based Fiber and Particle Materials

Flat-formed board products can be classified into two groups: (1) those primarily from fiber interfelted during manufacture with a predominantly natural bond, although extraneous material may be added to improve some property such as bond (or other strength property) and water resistance and (2) those made from distinct fractions of wood with the primary bond produced by an added bonding material.

Moldings, based on a composition of wood-based fiber or particle and binding material similar to those used for boards, have found increasing use.

Production statistics for molded units of fiber and wood particle are difficult to obtain because the units are used in such widely different commodities as toilet seats, croquet balls, school desktops and seats, frames for luggage, and armrests, door panels, and other molded components for automobiles. The number of uses for these moldings is increasing because they combine shape with adequate structural strength and durability for many uses. See *wood*.

Wood-Metal Laminates

Wood-metal laminates constitute a composite panel construction in which the core material is made up of a wood or wood-derivative slab to which metal facing sheets are adhesively bonded.

The core material is usually plywood or a composition board of wood fibers or chips compressed and bonded together to form a flat core slab. Balsa wood and insulation boards are frequently used as core materials where thermal insulation is a requirement.

The metal facing sheets may be steel, aluminum, stainless steel, porcelain enameled metals, rigidized metals, or metals with decorative finishes. Light-gauge metals are usually used, ranging in thickness from 0.25 to 1.5 mm depending upon the specific strength, stiffness, and service requirements.

Adhesives used in bonding the metal to the core material are selected to meet the desired service requirements. For most standard laminates, the adhesive is water-resistant and fungus-proof so that the panels may be subjected to exterior as well as interior exposure. Continuous surface temperatures may range from a minimum of -51°C to a maximum of 77°C , although specially prepared laminates are available for continuous use as high as 177°C .

Greater Stiffness

Wood-metal laminates are designed to utilize the best properties of each of the component parts providing a panel that is not only

light in weight but also has good structural strength and high flexural rigidity. Because the metal facing sheets are supported by a core material of substantial thickness, smooth flat panels free from waves and buckles are obtained with light-gauge metals.

Wood-metal laminates are limited in size only by the size of the press equipment and commercial sizes of the metal sheets and core material *available*.

The panels may be sawed to exact size from stock size sheets. Frequently, however, the facing sheets are fabricated prior to bonding to the core material to provide special edge details.

Applications

Wood-metal laminates are used extensively in the architectural building and transportation fields. Curtain wall panels, column enclosures, partition panels, fascia, and soffit panels are typical applications. Truck and trailer bodies, shipping containers, and railroad car partition panels and doors are common uses of the laminate. In general, wherever light weight, combined with high rigidity and structural strength, is prerequisite, wood-metal laminates may be used to good advantage.

Woods Metal

An alloy of 50% bismuth, 27% lead, 13% tin, and 10% cadmium, which melts at 66°C .

Woody Fracture

(1) A fracture surface having a coarsely fibrous texture. It usually reflects an elongated grain structure or large quantities of strangers of inclusions. (2) A macrostructure, found particularly in wrought iron and in extruded rods of aluminum alloys, that shows elongated surfaces of separation when fractured.

Woof

See weft.

Wool Grease

A brownish, waxy fat of a faint, disagreeable odor, obtained as a by-product in the scouring of wool. The purified grease was formally known as **degras** and was used for leather dressing, and lubricating and slushing oils, and in soaps and ointments; but it is now largely employed for the production of lanolin and its derivatives, chiefly for cosmetics. Wool grease contains **lanoceric acid**; **lanopalmic acid**, and **lanosterol**, a high alcohol related to cholesterol. Although these can be broken down into derivatives.

Lanolin is a purified and hydrated grease, also known as *lanain*, and in pharmacy as *lanum* and *adepts lanae*. It has a melting point of about 40°C and is soluble in alcohol. Lanolin is basically a wax consisting of esters of sterol alcohols combined with straight-chain fatty acids, and with only a small proportion of free alcohols. It contains about 95% of fatty acid esters, but its direct use as an emollient depends on the 5% of free alcohols and acids. However, more than 30 derivatives are obtained from lanolin, and these are used in blends to give specific properties to cosmetics. They are often marketed under trade names, and some of the ingredients may be synthesized from raw materials other than wool grease, or chemically altered from wool-grease derivatives.

A variety of products used in cosmetics and pharmaceuticals are made by fractionation or chemical alteration of lanolin. They are also useful in compounding plastics and industrial coating but are generally too scarce and expensive for these purposes. *Ethoxylated lanolin* and *ethoxylated lanolin alcohols* are used in water-soluble emulsions and conditioners. *Solulan* is a general trade name for these materials. *Lanolin oil* and *lanolin wax* are made by solvent fractionation of lanolin. *Viscolan* and *Waxolan* are these products. *Barium lanolate*, made by saponification, is used as an anticorrosion agent. It is antiphobic and is also used as an anticaking agent. In a 25% barium concentration, it is used for hard lubricating grease.

Wootz Process

An ancient steelmaking process that utilized the natural wind, suitably channeled, as an air blast for crucible smelting. The iron was then subjected to a cementation process.

Work Angle

The angle that the electrode makes with the referenced plane or surface of the base metal in a plane perpendicular to the axis of the weld. See also *drag angle* and *push angle*.

Work Angle (Pipe)

The angle that the electrode makes with the referenced plane extending from the center of the pipe through the molten weld pool. See the term *travel angle* (pipe).

Work Coil

The inductor used when welding, brazing, or soldering with induction heating equipment. See also *induction work coil* and the term inductor.

Work Connection

In welding, the connection of the work lead to the work.

Work Factor

A measure of the stability of a lubricant when subjected to an endurance test. The work factor is expressed as the average value of the ratio of three characteristics (viscosity, carbon residue, and neutralization number) as measured before the test to those same characteristics as measured after the test.

Work Lead

The electrical conductor connecting the source of arc welding current to the work. Also called work connection, welding ground, or ground lead.

Work Hardening

Same as *strain hardening*.

Workability

See *formability*.

Working

Causing permanent deformation to material. The terms “work” and “plastically deform” are effectively synonymous; the former tends to be used in a manufacturing context and the latter in an academic or mechanical testing context. Cold working refers to processes where no recrystallization occurs and the component work hardens, that is, becomes progressively harder, up to some limiting level, and less ductile. Hot working refers to a process, usually at elevated temperature, where deformation is accompanied by recrystallization, that is, no hardening occurs. Warm working is a special case of cold working involving deliberate heating, perhaps to assist deformation or minimize oxidation, but the temperature reached is insufficient to allow recrystallization.

Working Distance

The distance between the surface of the specimen being examined microscopically and the front surface of the objective lens.

Working Electrode

The test specimen electrode in an *electrochemical cell*.

Working Life

The period of time during which a liquid resin or adhesive, after mixing with catalyst, solvent, or other compounding ingredients, remains usable. See also *gelation* time and *pot life*.

Working Stress/Load

This usually means the safe working load or the associated stress.

Worm

An exudation (sweat) of molten metal forced through the top crust of solidifying metal by gas evolution. See also *zinc worms*.

Wormhole

Elongated forms of gas pores or blowholes, particularly in welds.

Woven Fabric

A material (usually a planar structure) constructed by interlacing yarns, fibers, or filaments to form such fabric patterns as plain, harness satin, and leno weaves. See the terms *basketweave* (composites), *crowfoot satin*, *eight-harness satin*, *leno weave*, and *plain weave*.

Woven Roving

A heavy glass fiber fabric made by weaving roving, or yarn bundles.

Wrap Forming

See *stretch forming*.

Wrap Seam

A depression or step in the surface finish of a reinforced plastic caused by the lap of the flexible mold or carrier strip after it is removed from the cured pultrusion. See also *pultrusion*.

W

Wrap-Around Bend

The bend obtained when a specimen is wrapped in a closed helix around a cylindrical mandrel.

Wrapped Bush (Bearing)

A thin-walled steel bush lined with a bearing alloy, or any other bearing bush made from strip.

Wrapping Test

A test in which wire or similar section is wound around a former or itself a specified number of times to assess its ductility.

Wringing Fit

A fit of nominally zero allowance.

Wrinkle

A surface imperfection in laminated plastics that has the appearance of a crease or fold in one or more outer sheets of the paper, fabric, or other base. Also occurs in vacuum bag molding when the bag is improperly placed, causing a crease.

Wrinkle Bend

A bend, usually in a tube, produced by forming one or, usually, more semi-circumferential corrugations along the side forming the bend inner surface. The process typically involves locally heating a narrow band on the intended inside of the bend. The tube is then bent a small amount. This is repeated a short distance along the tube until the required profile is achieved.

Wrinkle Depression

An undulation or series of undulations or waves on the surface of a pultruded composite part.

Wrinkling

A wavy condition obtained in deep drawing of sheet metal, in the area of the metal between the edge of the flange and the draw radius. Wrinkling may also occur in other forming operations when unbalanced compressive forces are set up.

Wrist Pin Bearing

The bearing at the crankshaft end of an articulated connecting rod in a “V” engine.

Wrought

Any material that has been shaped by a deformation process, as opposed to a casting.

Wrought and Cast Aluminum Alloy Designations

Systems for designating wrought and cast aluminum alloys that have been devised by the Aluminum Association in the United States and

the American National Standards Institute. For wrought alloys, a four-digit system is used to produce a list of wrought composition families as follows:

Aluminum, ≥99.00%	1xxx
Aluminum alloys and grouped by major alloying element(s):	
Copper	2xxx
Manganese	3xxx
Silicon	4xxx
Magnesium	5xxx
Magnesium and silicon	6xxx
Zinc	7xxx
Other elements	8xxx
Unused series	9xxx

Wrought Iron

Wrought iron is commercially pure iron made by melting white cast iron and passing an oxidizing flame over it, leaving the iron in a porous condition, which is then rolled to unite it into one mass. As those made, it has a fibrous structure, with fibers of slag through the iron and the direction of rolling. It is also made by the Aston process of shooting Bessemer iron into a ladle of molten slag. Modern wrought iron has a fine dispersion of silicate inclusions that interrupt the granular pattern and gives it a fibrous nature.

Structurally, wrought iron is a composite material; the base metal and the slag are in physical association, in contrast to the chemical or alloy relationship that generally exists between the constituents of other metals.

Originally iron of fairly high purity made by various smelting techniques followed by repeated forging to produce a tough, fairly corrosion resistant material suitable for major structures as well as decorative purposes. The *Puddling process* was the most common process in the United Kingdom. The *Aston* process was more common in the United States. Originally, wrought iron was a major structural material. However, it was superseded by steel of lower cost, higher strength and is available in much larger sizes. Consequently, these older processes are now commercially obsolete and current usage of the term “Wrought Iron” usually refers to mild steel bar bent in an aesthetically pleasing manner for functional or decorative applications.

The form and distribution of the iron silicate particles may be stringerlike, ribbonlike, or platelets. Practically, the physical effects of the incorporated iron silicate slag must be taken into consideration in bending and forming wrought iron pipe, plate, bars, and shapes, but when properly handled—cold or hot—fabrication is accomplished without difficulty.

Mechanical Properties

The value of wrought iron is in its corrosion resistance and ductility. It is used chiefly for rivets, staybolts, water pipes, tank plates, and forged work. Minimum specifications for ASTM wrought iron call for a tensile strength of 275 MPa, yield strengths of 165 MPa, and elongation of 12%, with carbon not over 0.08%, but the physical properties are usually higher. Wrought iron 4D has only 0.02% carbon with 0.12% phosphorus, and the fine fibers are of a controlled composition of silicon, manganese, and phosphorus. This iron has a tensile strength of 330 MPa, elongation 14%, and Brinell hardness 105. Manganese wrought iron has 1% manganese for higher impact strength.

Ordinary wrought iron with slag may contain frequent slag cracks, and the quality grades are now made by controlled additions of silicate, and with controlled working to obtain uniformity. But for tanks and plate work, ingot iron is now usually substituted.

The Norway iron formally much used for bolts and rivets was a Swedish charcoal iron brought to America in Norwegian ships. This iron, with as low as 0.02% carbon, and extremely low silicon, sulfur, and phosphorus, was valued for its great ductility and toughness and also for its permeability qualities for transformer cores. Commercial wrought iron is now usually ingot iron or fibered low-carbon steel.

The tensile properties of wrought iron are largely those of ferrite plus the strengthening affect of any phosphorus content, which adds approximately 6.8 MPa for each 0.01% above 0.10% of contained phosphorus. Strength, elasticity, and ductility are affected to some degree by small variations in the metalloid content and in even greater degree by the amount of the incorporated slag and the character of its distribution.

Nickel, molybdenum, copper, and phosphorus are added to wrought iron to increase yield and ultimate strengths without materially detracting from toughness as measured by elongation and reduction of area.

Fabrication

Forging

Wrought iron is an easy material to forge using any of the common methods. The temperature at which the best results are obtained lies in the range of 1149°C–1316°C. Ordinarily “flat and edge” working is essential for good results. Limited upsetting must be accomplished at “sweating to welding” temperatures.

Bending

Wrought iron plates, bars, pipe, and structural may be bent either hot or cold, depending on the severity of the operation, keeping in mind that bending involves the directional ductility of the material. Hot bending ordinarily is accomplished at a dull red heat (704°C–760°C) below the critical “red-short” range of wrought iron (871°C–927°C). The ductility available for hot bending is about twice that available for cold bending. Forming of flanged and dished heads is accomplished hot from special forming, equal property plate.

Welding

Wrought iron can be welded easily by any of the commonly used processes, such as forge welding, electrical resistance welding, electric metallic arc welding, electric carbon arc welding, and gas or oxyacetylene welding. The iron silicate or slag included in wrought iron melts at a temperature below the fusion point of the iron-base metal so that the melting of the slag gives the metal surface a greasy appearance. This should not be mistaken for actual fusion of the base metal; heating should be continued until the iron reaches the state of fusion. The siliceous slag content provides a self-fluxing action to the material during the welding operation.

Threading

The machinability or free-cutting characteristics of most ferrous metals are adversely influenced by either excessive hardness or softness. Wrought iron displays almost ideal hardness for good machinability, and the entrained silicate produces chips that crumble and clear the dies. Standard threading equipment that incorporates minor variations in lip angle, lead, and clearance is usually satisfactory with wrought iron.

Protective Coatings

Wrought iron lends itself readily to such cleaning operations as pickling and sandblasting for the application of protective coatings. Where protective coatings such as paint or hot-dipped metallic coatings are to be applied, the coatings are found to adhere more firmly to wrought iron and a thicker coat will be attained compared with other wrought ferrous metals. This is because the natural surface of wrought iron is microscopically rougher than other metals after cleaning, thus providing a better anchorage for coatings.

Corrosion Resistance

The resistance of wrought iron to corrosion has been demonstrated by long years of service life and many applications. Some have attributed successful performance to the purity of the iron-based, the presence of a considerable quantity of phosphorus or copper, freedom from segregation, to the presence of the inert slag fibers disseminated throughout the metal, or to combinations of such attributes.

In actual service, the corrosion resistance of wrought iron has shown superior performance in such applications as radiant heating and snow-melting coils, skating-rink piping, condenser and heat-exchanger equipment, and other industrial and building piping services. Wrought iron has long been specified for steam condensate piping where dissolved oxygen and carbon dioxide present severe corrosion problems. Cooling water cycles of the once-through and open-recirculating variety are solved by the use of wrought-iron pipe.

Applications

Building Construction

Hot and cold potable water, soil, waste, vent, and downspout piping; radiant heating, snow melting, air-conditioning cooling, and chilled-water lines; gas, fire protection, and soap lines; condensate and steam returns, ice-rink and swimming-pool piping; underground service lines and electrical conduit.

Industrial

Unfired heat exchangers, brine coils, condenser tubes, caustic soda, concentrated sulfuric acid, ammonia, and miscellaneous process lines; sprinkler systems, boiler feed and blowoff lines, condenser water piping, runner buckets, skimmer bars, smokestacks and standpipes, and salt and water well pipe and casing.

Public Works/Infrastructure

Bridge railings, fenders, blast plates, drainage lines and troughs, traffic signal conduit, sludge digester heating coils, aeration tank piping, sewer outfall lines, large outside diameter intake and discharge lines, trash racks, wire plates, dam gates, pier-protection plates, sludge tanks and lines, and dredge pipe.

Railroad and Marine

Tie spacer bars, diesel exhaust and air-brake piping, ballast and brine protection plates, brine, cargo and washed down lines on ships, hull and deck plating, rudders, fire screens, breechings, tanker heating coils, car retarder and yard piping, spring bands, car charging lines, nipples, pontoons, and car and switch deicers.

W

Others

Gas collection hoods, staybolts, flue gas conductors, sulfur mining gut, air and transport lines, coal-handling equipment, chlorine, compressed air lines, distributor arms, cooling tower, and spray pond piping.

Wrought iron is available in the form of plates, sheets, bars, structural, forging blooms and billets, rivets, chain, and a wide range of tubular products, including pipe, tubing and casing, electrical conduit, cold-drawn tubing, and welded fittings.

Wrung Fit

See *interference fit*.

Wüstite

Iron oxide, FeO.

X-Axis

In reinforced plastic laminate, an axis in the plane of the laminate that is used as the 0° reference for designating the angle of a lamina. See also *laminate* and the term *quasi-isotropic laminate*.

Xenon

One of the noble or inert gases and a rare gas (symbol Xe; atomic number 54) that is used in photographic flash lamps, luminescent tubes, and lasers.

Xerography

A technique for producing photocopies.

X-Ray

(1) A penetrating electromagnetic radiation, usually generated by accelerating electrons to high velocity and suddenly stopping them by collision with a solid body. Wavelengths of x-rays range from about 10^{-1} to 10^2 Å, the average wavelength used in research being about 1 Å. Also known as roentgen ray or x-radiation. (2) Electromagnetic radiation of less than 500 Ångstrom units emitted by decelerated electrons. See also *electromagnetic radiation*.

X-Ray Diffraction

(1) An analytical technique in which measurements are made of the angles at which x-rays are preferentially scattered from a sample (as well as of the intensities scattered at various angles) in order to deduce information on the crystalline nature of the sample—its crystalline structure, orientations, and so on. (2) Techniques utilizing the diffraction of x-rays, particularly to investigate crystal structures. The wavelength of x-rays is of the same order as the lattice spacing of metal crystals, so if an x-ray beam is directed at a crystal, the regular spacing of the planes of atoms causes diffraction effects that can be recorded on photographic film. The diffraction patterns can provide information on lattice spacings, extent of cold working and material composition, etc. See *Bragg* and *von Laue*.

X-Ray Diffraction Residual Stress Techniques

Diffraction method in which the strain in the crystal lattice is measured, and the residual stress producing the strain is calculated assuming a linear elastic distortion of the crystal lattice. See also *macroscopic stress*, *microscopic stress*, and *residual stress*.

X-Ray Emission Spectroscopy

Pertaining to *emission spectroscopy* in the x-ray wavelength region of the electromagnetic spectrum.

X-Ray Fluorescence

Emission by a substance of its characteristic x-ray line spectrum on exposure to x-rays.

X-Ray Fluorescence Spectroscopy

An analytical technique in which a beam of x-rays excites the characteristic radiation of elements in the item of interest. The radiation from the individual constituents is then measured in a spectrometer.

X-Ray Map

An intensity map (usually corresponding to an image) in which the intensity in any area is proportional to the concentration of a specific element in that area.

X-Ray Photoelectron Spectroscopy

An analytical technique that measures the energy spectra of electrons emitted from the surface of a material when exposed to monochromatic x-rays.

Carbon black-filled rubber parts may challenge many analytical methods because the compounded rubber may include up to 20 individual ingredients. Often, after mixing, it is difficult to extract ingredients from the polymer base because of their interactions with other ingredients such as carbon black.

Testing of bonded rubber-to-metal parts amplifies the problem twofold. The bonding adhesive is also a multicomponent polymeric blend, much like the rubber. Also involved are contaminants associated with the substrate. For example, a stamped steel insert may be contaminated with hydrocarbons. If the metal is porous, oil may bleed out of the metal grain over time and undermine a bond system. Or, if the oil is present initially, it may prevent adhesive wet-out, thus inhibiting adhesion to the substrate.

Disadvantages

Some techniques such as reflectants, Fourier transform infrared spectrometer, and energy dispersive x-ray (EDS) would not be adequate for testing rubber bonded to metal. EDS, using a windowless system, does not have sufficient resolution for lower-weight elements.

Process

To gain the most definitive picture of failed bonded surfaces, scanning electron microscopy and x-ray photoelectron spectroscopy (XPS or ESCA) methods have proven the most valuable.

XPS is an excellent method for determining chemical composition of a surface. This method penetrates the surface of the sample to a depth of only 50 Å. XPS measures the binding energies of the atoms present on the surface, yielding a very distinctive signature of the atomic species present. XPS is sensitive enough to generate signals that provide both a quantitative and qualitative picture of the

X

surface composition over a wide elemental range. Computer analysis techniques convert these signals to atomic percentages to allow reconstruction of the various materials present.

Case Study

The following case study analyzes black rubber bonded to a steel part. The part was exposed to a hostile environment (hydrocarbon fluids at 150°C) for a relatively short period of time before failure occurred. Parts of this type are expected to last approximately 8 years; this part failed in under 6 months.

Initial visual analysis indicated failure primarily in an adhesive mode. However, no apparent cause of the failure was easily identifiable. Gaining a clear understanding of the cause of the adhesive failure at this point was difficult because the part was saturated with hydrocarbon oil.

The cross section of the remaining bonded area indicated that under normal conditions, the adhesive could not be distinguished from the rubber. This would indicate a high degree of commingling is necessary between rubber and adhesive to achieve a good bond.

At this point, the unbond was believed to be caused by the overbaking of the adhesive. In this situation, the poor bond is due to premature cross-linking of the adhesive prior to the application of rubber. The cross-linking of the adhesive causes mechanisms for adhesion to be compromised and inhibits physical interaction.

To confirm this, both a control part, with bond failure due to adhesive overbake, and the failed part were subjected to analysis by XPS. Only failed mating surfaces were examined by this method. Typical areas scanned by this method were 1×3 mm. It is not necessary to neutralize with the electron gun due to only minimal charging effects. Only a single sample was tested for each condition.

The XPS analysis of the mating surfaces of the defective part showed the surfaces to be very similar in elemental composition. Values from the failed part, when compared with the control part, indicated the hydrocarbon fluid did not affect the analysis. This is most likely because the high vacuum necessary in this testing technique removed the hydrocarbon fluid from the surface.

The trace elements present in analysis of both surfaces of both parts support the conclusion that the parts failed by the same mechanism. Test results support the idea that both samples failed in a boundary layer between the rubber and the adhesive. Trace elements, known not to be native to the rubber compound, indicate the source to be the adhesive.

From the presence of adhesive components on all mating surfaces tested, we can effectively eliminate contamination as the cause of the unbond. The presence of the adhesive and the pulled-out material present on the failed part would indicate that the part may have been weakly bonded. Finally, the evident lack of adhesive and rubber interspersions would indicate one or both components had achieved sufficient viscosity to resist flow. The combined evidence using XPS tends to support our initial observation that all adhesives had prematurely cross-linked. These data allow the cause to be correctly identified and will help produce a more robust part and processing in the future.

X-Ray Spectrograph

A photographic instrument for x-ray emission analysis. If the instrument for x-ray emission analysis does not employ photography, it is better described as an x-ray spectrometer.

X-Ray Spectrometry

Measurement of wavelengths of x-rays by observing their diffraction by crystals of known lattice spacing.

X-Ray Spectrum

The plot of the intensity or the number of x-ray photons versus energy (or wavelength).

X-Ray Technology

As with medical x-ray instruments, there are analytical x-ray measurements that can produce images of internal structures of objects that are opaque to visible light. There are instruments that can determine the chemical elemental composition of an object, which can identify the crystalline phases of a mixture of solids, and others that determine the complete atomic and molecular structures of a single crystal. The determination of particle size and structural information for fibers and polymers and the study of stress, texture, and thin films are x-ray applications that are growing in importance.

Characteristics and Generation of X-Rays

X-Ray Electromagnetic Spectrum

X-rays are a form of electromagnetic radiation and have a wavelength, λ , much shorter than visible light. The center of the visible light spectrum has a wavelength of about 0.56×10^{-6} m. The most commonly used methods for generating x-rays are the synchrotron and x-ray tubes.

Synchrotron Radiation

X-rays are produced when very energetic electrons traveling close to the speed of light are decelerated. In synchrotrons, electrons are accelerated with electromagnets while traveling along a linear path. Then, they are inserted into a nearly circular path, which is maintained by bending magnets.

X-Ray Tubes

X-ray tubes are the most widely used source for the generation of x-rays. In these tubes, electrons are accelerated by a high electric potential (20–120 kV). These electrons strike the target (anode) of the tube and decelerate as they pass through the electron clouds of the atoms. This phenomenon produces a continuous spectrum similar, but much less intense, to that of the synchrotron. In addition, some high-energy electrons knock electrons out of the atomic orbitals of the atoms of the target material. When these orbitals are refilled by electrons, x-ray photons are generated. The resulting x-ray spectrum of intensity versus wavelength has a series of peaks known as characteristic lines.

The materials that are used as targets in x-ray tubes depend on the application.

Applications

X-ray applications can be placed into three categories:

1. X-ray radiography permits the imaging of the internal structure of an object (e.g., bones of a hand). It is based on the comparative observance of photons as they travel through the different materials making up the object.

2. X-ray fluorescence spectrometry consists of the measurement of the incoherent scattering of x-rays. It is used primarily to determine the elemental composition of a sample.
3. X-ray diffraction consists of the measurement of the coherent scattering of x-rays. X-ray diffraction is used to determine the identity of crystalline phases in a multiphase powder sample and the atomic and molecular structures of single crystals. It can also be used to determine structural details of polymers, fibers, thin films, and amorphous solids and to study stress, texture, and particle size.

X-Ray Fluorescence Spectrometry

X-ray fluorescence spectrometry is a technique for measuring the elemental composition of samples. The basis of the technique is the relationship between the wavelength or energy of the emitted incoherently scattered x-ray photons and the atomic number of the element. When an atom is bombarded with x-ray photons of sufficient energy, an inner-orbital electron may be displaced, leaving the atom in an excited state. The atom can return to the ground state by transfer of a higher orbital electron into the vacancy (the resulting higher-level vacancy is filled by an electron from a still higher level). In so doing, the difference in energy between the electron ousted from the lower shell and the energy of the higher orbital electron is emitted as an x-ray photon. Each element produces a fluorescence spectrum of intensity versus wavelength that is characteristic of that element.

X-Ray Radiography

X-ray imaging tests are widely used to examine interior regions of metal castings, fusion welds, composite structures, and brazed components. Radiographic tests are made on pipeline welds, pressure vessels, nuclear fuel rods, and other critical materials and components that may contain 3D voids, inclusions, gaps, or cracks. Since penetrating radiation tests depend upon the absorption properties of materials on x-ray photons, the tests can reveal changes in thickness and density and the presence of inclusions in the material.

X-ray fluoroscopy is used for direct online examination. A fluorescent screen is used to convert x-ray photons into visible light photons. A television camera receives the visible image and displays it on a television screen. This type of system is used for security screening of carry-on luggage at airports.

As in medical x-ray imaging, computerized tomography can reveal the details of the internal structure of complex objects. Many detectors are used to measure the transmittance of x-rays along many lines through the object. A computer uses this information to produce an image of the internal structure of a slice of the object.

X-Ray Topography

A technique that comprises topography and x-ray diffraction. The term topography refers to a detailed description and mapping of physical (surface) features in a region. In the context of the x-ray diffraction, topographic methods are used to survey the lattice structure and imperfections in crystalline materials.

X-Ray Tube

A device for the production of x-rays by the impact of high-speed electrons on a metal target.

Xylene

Xylenes and ethylbenzene and C_8 aromatic isomers with the molecular formula C_8H_{10} . Xylenes consist of three isomers: *o*-xylene (OX), *m*-xylene, and *p*-xylene (PX). These differ in the positions of the two methyl groups on the benzene ring.

Uses

The majority of xylenes that are mostly produced by catalytic reforming or petroleum functions are used in motor gasoline. The majority of the xylenes that are recovered for petrochemical use are used to produce PX and OX. PX is the most important commercial isomer.

Xylylene Polymers

In a process capable of producing pinhole-free coatings of outstanding conformality and thickness uniformity through the unique chemistry of PX, a substrate is exposed to a controlled atmosphere of pure gaseous monomer. The coating process is best described as a vapor deposition polymerization. The monomer molecule is thermally stable but kinetically very reactive toward polymerization with other molecules of its kind. Although it is stable as a rarefied gas, upon condensation, it polymerizes spontaneously to produce a coating of high-molecular-weight, linear poly (*p*-xylylene).

Applications

Because the parylenes are generally insoluble in most solvents, even at elevated temperatures, they cannot be used as solvent-based coatings; neither can they be cast as films nor spun as fibers from solution.

The most important application of parylenes is as a conformal coating for printed wiring assemblies. These coatings provide excellent chemical resistance and resistance to fungal attack. In addition, they exhibit stable dielectric properties over a wide range of temperatures.

The use of parylenes as a hybrid circuit coating is based on much the same rationale as its use in circuit boards. A significant distinction lies in obtaining adhesion to the ceramic substrate material, the success of which determines the eventual performance of the coated part. Adhesion to the substrate must be achieved using adhesion promoters, such as the organosilanes.

Parylenes are superior candidates for dielectrics and high-quality capacitors. Their dielectric constant and loss remain constant over a wide temperature range. The thermistor sensing probe of a disposable bathythermograph is coated with parylene. This instrument is used to chart the ocean water temperature as a function of depth.

Parylene is used in the manufacture of high-quality miniature stepping motors, such as those used in wristwatches, and as a coating for the ferrite cores of pulse transformers, magnetic tape recording heads, and miniature inductors.

Use of parylene in the medical field is linked to electronics, for example, as a protective conformal coating on pacemaker circuitry.

As books age, the paper of their pages becomes brittle. A relatively thick coating of parylene can make these embrittled pages stronger.

X

By separating the coating from the substrate after deposition, the unique coating features of parylenes, especially continuity and thickness control and uniformity, can be imparted to a freestanding film. Applications include optical beam splitters, a window for a micrometeoroid detector, a detector cathode $4n$ x-ray streak camera, and windows for x-ray proportional counters.

Parylenes can be used for contamination control, that is, securing small particles to prevent them from damaging a surface in

a sealed unit, barrier coating, coating for corrosion control, and as dry lubricants.

XY Plane

In reinforced plastic laminates, the reference plane parallel to the plane of the laminate.

Yarns

Yarns are assemblages or bundles of fibers twisted or laid together to form continuous strands. They are produced with either filaments or staple fibers. Single strands of yarns can be twisted together to form ply or plied yarns, and ply yarns in turn can be twisted together to form cabled yarn or cord. Important yarn characteristics related to behavior are fineness (diameter or linear density) and the number of twists per unit length. The measure of fineness is commonly referred to as yarn number. Yarn numbering systems are somewhat complex, and they are different for different types of fibers. Essentially, they provide a measure of fineness in terms of weight per unit or length per unit weight.

Cotton yarns are designated by numbers, or counts. The standard count of cotton is 840 yd/lb. Number 10 yarn is therefore 8,400 yd/lb. A No. 80 sewing cotton is 80×840 , or 67,200 yd/lb.

Linen yarns are designated by the lea of 300 yd. A 10-count linen yarn is 10×300 , or 3000 yd/lb.

The size or count of spun rayon yarns is on the same basis as cotton yarn. The size or count of rayon filament yarn is on the basis of the denier, the rayon denier being 450 m weighing 5 cg. If 450 m of yarn weighs 5 cg, it has a count of 1 denier. If it weighs 10 cg, it is No. 2 denier. Rayon yarns run from 15 denier, the finest, to 1200 denier, the coarsest.

Reeled silk yarn counts are designated in deniers. The international denier for reeled silk is 500 m of yarn weighing 0.05 g. If 500 m weighs 1 g, the denier is No. 20. Spun silk count under the English system is the same as the cotton count. Under the French system, a count is designated by the number of skeins weighing 1 kg. The skein of silk is 1000 m.

A ply yarn is one that has two or more yarns twisted together. A two-ply yarn has two separate yarns twisted together. The separate yarns may be of different materials, such as cotton and rayon. A six-ply yarn has six separate yarns. A ply yarn may have the different plies of different twists to give different effects. Ply yarns are stronger than single yarns of the same diameter. Tightly twisted yarns make strong, hard fabrics. Linen yarns are not twisted as tightly as cotton because the flax fiber is longer, stronger, and not so fuzzy as the cotton. Filament rayon yarn is made from long, continuous rayon fibers, and it requires only slight twist. Fabrics made from filament yarn are called twalle. Monofilament is fiber heavy enough to be used alone as yarn, usually more than 15 denier. Tow consists of multifilament reject strands suitable for cutting into staple lengths for spinning. Spun rayon yarn is made from staple fiber, which is rayon filament cut into standard short lengths.

Yarn Bundle

See *bundle*.

Y-Axis

In composite laminates, the axis in the plane of the laminate that is perpendicular to the *x*-axis. See also *x*-axis.

Y-Block

A single *keel block*.

Yellow Brass/Metal

Any brass particularly as castings. A name sometimes used in reference to the 65Cu–35Zn type of brass, and sometimes the term refers specifically to brass with 60% copper and 40% zinc.

Yield

(1) Evidence of plastic deformation in structural materials. Also known as plastic flow or creep. See also *flow*. (2) The ratio of the number of acceptable items produced in a production run to the total number that was attempted to be produced. (3) Comparison of casting weight to the total weight of metal poured into the mold. (4) To suffer permanent deformation. See *tensile test*.

Yield Extension

The amount of extension between the upper and lower yield points. See *tensile test*.

Yield Point

The first stress in a material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. Only certain materials—those that exhibit a localized, heterogeneous type of transition from elastic to plastic deformation—produce a yield point. If there is a decrease in stress after yielding, a distinction may be made between upper and lower yield points. The load at which a sudden drop in the flow curve occurs is called the upper yield point. The constant load in the flow curve is the lower yield point.

The level of stress and strain at which a material suffers permanent deformation. See *tensile test*.

Yield Point Elongation

In materials that exhibit a yield point, the difference between the elongation at the completion and at the start of discontinuous yield.

Yield Strength

The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many materials, particularly metals. Compare with *tensile strength*.

Yield Stress

The stress level of highly ductile materials at which large strains take place without further increase in stress.

Y

Yield Value

The stress (either normal or shear) at which a marked increase in deformation occurs without an increase in load.

Young's Modulus

(1) A term used synonymously with modulus of elasticity. The ratio of tensile or compressive stresses to the resulting strain. (2) The elastic modulus—see *tensile test*. See also *modulus of elasticity*.

Ytterbium

A metallic element, one of the rare earth groups.

Yttrium and Alloys

A chemical element, yttrium (symbol Y, atomic number 39, atomic weight 88.905) resembles the rare earth elements closely. The stable isotope yttrium-89 constitutes 100% of the natural element, which is always found associated with the rare earths and is frequently classified as one.

Yttrium forms a white oxide, Y_2O_3 , which dissolves in acid to form trivalent yttrium salts. Yttrium has become commercially important since 1964. Yttrium forms the matrix for the europium-activated yttrium phosphors. These phosphors, when excited by electrons, emit a brilliant, clear-red light. The television industry uses these phosphors in manufacturing television screens. It is claimed that this phosphor gives better color reproduction and a much brighter screen than did the older non-rare-earth red phosphor. Also, the yttrium iron garnets, $Y_3Fe_5O_{12}$, and other garnets have found important uses in radar and communication devices. They transmit shortwave energy with very small losses.

Yttrium metal absorbs hydrogen, and in alloys up to a composition of YH_2 , they resemble metals very closely. In fact, in certain composition ranges, the alloy is a better conductor of electricity than the purer metal. The density of hydrogen near the YH_2 composition is greater per cubic centimeter than it is in water or liquid hydrogen; therefore, such alloys make excellent potential moderators for nuclear reactors. Also, these alloys can be heated to a white heat (about 1260°C) before the vapor pressure of hydrogen exceeds 1 atm (10² kPa), and therefore the moderator in the reactor can be operated at very high temperatures. Yttrium metal has a low nuclear cross section, so it is also a potential structural material for reactors of the future.

Yttrium is used commercially in the metal industry for alloy purposes and as a “getter” to remove oxygen and nonmetallic impurities in other metals. Radioactive yttrium isotopes have been used in attempts at treating cancer.

Yttrium Aluminum Garnet

Yttrium aluminum garnet has the formula $Y_3Fe_5O_{12}$; its crystals are capable of sustaining laser activity when doped with neodymium.

Yttrium Oxide

This oxide (Y_2O_3) has a melting point of 2685°C, a density of 5.03 g/cm³, and is soluble in acids, but only slightly soluble in water.

Yttrium is not a rare earth but always occurs with them in minerals because of similar general chemistry. Applications are in electrically conducting ceramics, refractories, insulators, phosphors, glass, special optical glasses, and other ceramics.

White powder has cubic crystal structure and small amounts of dysprosium oxide, gadolinium oxide, and terbium oxide as impurities.

Yttria can be compounded into polycrystalline as well as single-crystal garnets for use in microwave generation and detection devices. Such materials are important to microwave technology because they exhibit both good dielectric and magnetic properties, which can be controlled through compositional variations.

Yttria-stabilized zirconia can be used to produce a high-quality diamond substitute for jewelry or a rugged sensor for measuring oxygen in automotive exhaust, depending on the method of fabrication. Nd/yttrium aluminum garnet single crystal rods find many applications as lasers in industry and research.

Y_2O_3 can be used (with scandium, lanthanum, and cesium oxides) with TiO_2 bodies for better control of properties than with alkaline earths. In combination with europium oxide, yttria is used to make the red phosphor in color television picture tubes. Combined with ZrO_2 , it makes good high-temperature refractories. It is also used in silicon nitride as a sintering aid.

Yttria is a rare earth oxide that is added in small amounts (0.5–1.3 wt.%) to nickel-base powder metallurgy superalloy compositions in order to improve their high-temperature creep resistance and oxidation resistance. Such alloys are referred to as oxide-dispersion-strengthened alloys. Yttria is also an additive to ceramic compositions, most notably zirconia. See also *dispersion-strengthened material*, *mechanical alloying*, and *zirconia*.

Y-TZP

Yttria tetragonal zirconia polycrystalline (Y-TZP) is a fine-grained ceramic used in special engineering applications that benefit from its high density, excellent wear resistance, and fine grain size, such as fiber-optic ferrules. High-purity fine reactive coprecipitated zirconia powders containing 3 mol% yttria are used to produce Y-TZP ceramics.

ZAF Corrections

A quantitative x-ray program that corrects for atomic number (Z), absorption (A), and fluorescence (F) effects in a matrix.

Z-Axis

In laminates, the reference axis normal to the xy plane of the laminate.

Zeeman Effect

A splitting of the degenerate electron energy level into states of slightly different energies in the presence of an external magnetic field. This effect is useful for background correction in *atomic absorption spectrometry*.

Zero Bleed

A laminate fabrication procedure that does not allow loss of resin during cure. Also describes prepreg made with the amount of resin desired in the final part, such that no resin has to be removed during cure. See also *laminate* and *prepreg*.

Zero Time

The time at which the given loading or constraint conditions are initially obtained in creep and stress-relaxation tests, respectively.

Zeta Potential

See *electrokinetic potential*.

Ziegler–Natta Catalysts

Initially, a catalyst consisting of an alkylaluminum compound with a compound of the titanium group of the periodic table, a typical combination being triethylaluminum at either titanium tetrachloride or titanium trichloride. Subsequently, an enormous variety of such mixtures is used in polymerization to provide stereospecificity (isotactic or syndiotactic). See also *isotactic stereoisomerism* and *syndiotactic stereoisomerism*.

Zinc and Alloys

A bluish-white crystalline metal, zinc (symbol Zn) has a specific gravity of 7.13, melts at 420°C, and boils at 906°C. The commercially pure metal has a tensile strength, cast, of about 62 MPa with an elongation of 1%, and the rolled metal has a strength of 165 MPa with an elongation of 35%. But small amounts of alloying elements harden and strengthen the metal, and it is seldom used alone.

Zinc is seldom used alone except as a coating. In addition to its metal and alloy forms, zinc also extends the life of other materials such as steel (by hot dipping or electrogalvanizing), rubber and

plastics (as an aging inhibitor), and wood (in paints). Zinc is also used to make brass, bronze, and nickel silver; die-casting alloys in plate, strip, and coil; foundry alloys; superplastic zinc; and activators and stabilizers for plastics. Additionally, zinc is used for electric batteries, for die castings, and in alloyed sheets for flashings, gutters, and stamped and formed parts. The metal is harder than tin, and an electrodeposited plate has a Vickers hardness of about 45. Zinc is also used for many chemicals.

Production

The metallurgy of zinc is dominated by the fact that its oxide is not reduced by carbon below the boiling point of the metal.

A large fraction of the world's zinc is still produced from relatively small horizontal retorts with one furnace (or bank) containing hundreds of such units.

Other large, continuously operated vertical retorts have operated with top charging of briquettes of zinc oxide and bituminous coal and metal tapping from an outside condenser.

Another continuous method involves electrothermic reduction, using a novel condenser in which the retort vapors are sucked through molten zinc.

Neither horizontal or vertical retorts nor electrothermic units nor blast furnaces normally produce zinc of the extreme high purity required by much of the total market for zinc. Since 1935, a redistillation process has been used as the thermal means of meeting this demand. The principles of fractional distillation are utilized, and zinc of 99.99+% purity is made.

There is also an electrolytic method of producing metallic zinc. Because the selective flotation process made additional quantities of zinc concentrates available in localities where electric power is cheap, the production of electrolytic zinc was increased.

In the electrolytic process, the zinc content of the roasted ore is leached out with dilute sulfuric acid. The zinc-bearing solution is filtered and purified and the zinc content recovered from the solution by electrolysis, using lead alloy anodes and sheet aluminum cathodes. Current passing through the electrolytic cell, from anode to cathode, deposits the metallic zinc on the cathodes from which it is stripped at regular intervals, melted, and cast into slabs. Zinc so produced is 99.9+ or 99.99+% pure depending on need and the process control exercised.

Compounds and Zinc Forms

Zinc is always divalent in its compounds, except for some of those with other metals, which are classed as zinc alloys. Most of the more important zinc compounds are inorganic, since they are much more widely used than the organic zinc compounds.

The old name "spelter," often applied to slab zinc, came from the name "spailter" used by Dutch traders for the zinc brought from China.

Sterling spelter was 99.5% pure. Special high-grade zinc is distilled, with a purity of 99.99%, containing no more than 0.006% lead and 0.004% cadmium. High-grade zinc, used in alloys for die casting, is 99.9% pure, with 0.07 max lead. Brass special zinc

Z

is 99.10% pure, with 0.6 max lead and 0.5 max cadmium. Prime western zinc, used for galvanizing, contains 1.60 max lead and 0.08 max iron. Zinc crystals produced for electronic uses are 99.999% pure metal.

On exposure to the air, zinc becomes coated with a film of carbonate and is then very corrosion resistant. Zinc foil comes in thicknesses from 0.003 to 0.015 cm. It is reduced by electrodeposition on an aluminum drum cathode and stripping off on a collecting reel. But most of the zinc sheet contains a small amount of alloying elements to increase the physical properties. Slight amounts of copper and titanium reduce grain size in sheet zinc. In cast zinc, the hexagonal columnar grain extends from the mold face to the surface or to other grains growing from another mold face, and even very slight additions of iron can control this grain growth. Aluminum is also much used in alloying zinc. In zinc used for galvanizing, a small addition of aluminum prevents formation of brittle alloy layer, increases ductility of the coating, and gives a smoother surface. Small additions of tin give bright spangled coatings.

Zinc has 12 isotopes, but the natural material consists of 5 stable isotopes, of which nearly half is zinc-64. The stable isotope zinc-67, occurring to the extent of about 4% in natural zinc, is sensitive to tiny variations in transmitted energy, giving off electromagnetic radiations that permit high accuracy in measuring instruments. It measures gamma-ray vibrations with great sensitivity and is used in the nuclear clock.

Zinc powder, or zinc dust, is a fine gray powder of 97% minimum purity usually in 325-mesh particle size. It is used in pyrotechnics, in paints, and in rubbers, used as a reducing agent and catalyst and as a secondary dispersing agent, and used to increase flexing and to produce sherardized steel.

In paints, zinc powder is easily wetted by oils. It keeps zinc oxide in suspension and also hardens the film. Mossy zinc, used to obtain color effects on face brick, is a spangly zinc powder made by pouring the molten metal into water. Feathered zinc is a fine grade of mossy zinc. Photoengraving zinc for printing plates is made from pure zinc with only a small amount of iron to reduce grain size and is alloyed with not more than 0.2% each of cadmium, manganese, and magnesium. Cathodic zinc, used in the form of small bars or plates fastened to the hulls of ships or to underground pipelines to reduce electrolytic corrosion, is zinc of 99.99% purity with iron less than 0.0014% to prevent polarization.

Applications

For many years, the greatest use of zinc has been to protect iron and steel against atmospheric corrosion. Because of the relatively high electropotential of zinc, it is anodic to iron. If zinc and iron or steel are electrically connected and are jointly exposed in most corrosive media; the steel will be protected, while the zinc will be attacked preferentially and sacrificially. This, along with the fact that zinc corrodes far less rapidly than iron in most environments, forms the basis for one of the great fields of use of zinc and galvanizing (by hot dipping or electrolytically), metallizing, and sherardizing, in zinc-pigmented paints systems, as anodes in systems for cathodic protection. The six techniques are described in the succeeding text.

Hot-Dip Galvanizing

Zinc alloys are readily compatible with iron. Therefore, steel articles, suitably cleaned, will be wet by molten zinc and will acquire uniform coatings of zinc, the thickness of which will vary with time, temperature, and rate of withdrawal. Such coats are continuous and reasonably ductile. Ductility is improved considerably by the

restriction of immersion time and by the addition of small amounts of aluminum to the galvanizing bath.

Millions of tons of steel products are protected by zinc annually. The time before first rusting of the iron or steel base is proportional to the thickness of zinc coat, which in turn is subject to control—depending on product and processing—within a range from thin wiped coats on some products to as much as 0.20 mm on certain low-alloy steels allowed to acquire a full natural coat.

The usefulness of zinc as a coating material comes from its dual ability to protect, first as a long-lasting sheath, and then sacrificially when the sheath finally is perforated.

Electrogalvanizing

Zinc may be electrolytically deposited on essentially all iron and steel products. Wire and strip are commonly so treated as are many fabricated parts. Electrodeposited coats are ductile and uniform but normally are thinner and therefore find applications in less rigorous service.

Metallizing

Zinc wire or powder is melted and sprayed on suitably grit-blasted steel surfaces—a growing use. Its virtues are flexibility in application and substantial thicknesses that may be applied. The method is particularly useful for renewal of heavy coatings on areas exposed to particularly critical corrosive conditions and the coating of parts too large for hot dipping. Although metallized coats may be somewhat porous, the sacrificial nature of zinc nevertheless makes them protective. Suitable pore sealants may be used as a part of a metallizing system.

Sherardizing

Zinc powder is packed loosely around clean parts to be sherardized in an airtight container. When sealed, heated to temperature near but below the zinc melting point, and then slowly rotated, the zinc alloys with the steel to form a thin, abrasion-resistant, and uniform protective coating (0.4–1.8 g/cm²).

Sherardizing is used commonly to coat small items such as nuts, bolts, and screws; an exception is tubular electrical conduit. Sherardized coats receive varnish, tanks, and lacquers particularly well.

Zinc-Pigmented Paints

Evidence has accumulated to demonstrate that paints heavily pigmented with zinc dust perform similarly to zinc coats otherwise applied. Electrical contact must exist between the steel and the zinc-dust particles, consequently, special vehicles that must be used and the steel surface must be clean.

Zinc Anodes

High-purity zinc, normally alloyed with small additions of aluminum, with or without cadmium, is cast or rolled into anodes that, when electrically bonded to bare or painted steel, will protect large areas from the corrosive attack of such environments as seawater. The advantages of zinc in this application include self-regulation (no more current is generated than is required), a minimum generation of hydrogen, and long life. This is a growing application for the protection of ship hulls, cargo tanks in ballast, piers, pilings, etc.

General Comment

Reference has been made to the importance of coating thickness—the heavier the coat, the longer the time before first rusting.

All evidence at hand indicates that the amount of zinc in a coat is the controlling factor and the method of application is of secondary importance. Uniformity of coat and adhesion must be good. No data are known to demonstrate that common zinc impurities normally present in amounts to or slightly above specification limits have any significantly deleterious or beneficial influence on the ability of zinc to protect iron or steel against atmospheric corrosion. Although any greater zinc may be used for galvanizing, Prime Western is the one most commonly employed.

Die casting is a market for zinc that may soon become its largest market. These alloys melt readily, are highly fluid, and do not attack steel dies or equipment. When used under good temperature control and with good die design practices, casting surfaces are excellent and easily finished. Physical properties are good, and dimensional stability is excellent.

Alloy control within the specified limits ensures long life. Low aluminum results in decreased casting and mechanical properties and adversely affects the performance of plated coatings. High aluminum can lead to brittleness (an alloy eutectic forms at 5% aluminum). High copper content decreases dimensional stability. Iron is commonly encountered is not critical. Lead, tin, and cadmium, if present above specification limits, can lead to intercrystalline corrosion with objectionable growth and serious cracking or brittleness as a result. Magnesium minimizes the deleterious influence of lead, tin, or cadmium but at or near specification maximum decreases ductility and castability and can lead to objectionable hot shortness. Other impurities such as chromium and nickel, which may be encountered, are not critical.

Zinc die castings are used by the automotive, truck, and bus industry for functional, decorative-functional, or decorative purposes. A majority is plated with copper-nickel-chromium in a variety of plating systems especially adapted to withstand severe service conditions.

Other major outlets for zinc die casting include household appliances, business machines, machine tools, air-brake systems, and communication equipment.

Even such nonstructural materials as cardboard can be zinc coated by low-temperature flame spraying. Other important uses of zinc are in brass and zinc die-casting alloys, in zinc sheet and strip, in electrical dry cells, in making certain zinc compounds, and in chemical preparations.

A so-called tumble-plating process coats small metal parts by applying zinc powder to them with an adhesive, then tumbling them with glass beads, to roll out the powder into a continuous coat of zinc. Rechargeable nickel-zinc batteries offer higher energy densities than conventional dry cells. Foamed zinc metal has been suggested for use in lightweight structures such as aircraft and spacecraft. Some other uses of zinc are in dry cells, roofing, lithographic plates, fuses, organ pipes, and wire coatings.

Zinc is believed to be needed for normal growth and development of all living species, including humans; actually, life without zinc would be impossible. Zinc is a common element that is present in virtually every type of human food, and zinc deficiency is therefore not considered to be a common problem in humans. Zinc is a trace element that is present in biological fluids at a concentration below 1 ppm, and only a small amount (normally < 25 mg) is required in the daily diet. (The recommended daily allowance for zinc is 15 mg/day for adults and 10 mg/day for growing children.) It is relatively nontoxic, without noticeable side effects at intake levels of up to 10 times that normal daily requirement.

The adult human body contains approximately 2 g of zinc distributed in all cells but especially in bones and muscle. It occurs almost exclusively in association with other molecules, typically proteins,

where it exists as a divalent ion Zn^{2+} . Many of the zinc-containing proteins are enzymes, known as metalloenzymes, in which the zinc is bound to three amino acid side chains and a molecule of water. Zinc metalloenzymes are involved in most of the key steps of the replication, transcription, and translation of genetic material; hence, they are critical for growth and development. They also help catalyze all major pathways of metabolism, as well as many specialized reactions.

Many biological processes seem to have a relationship to zinc metabolism, although they are undefined. The oxide has been used since the first century for treatment of skin rashes. Zinc has also been found to be helpful in other skin disorders such as burns, acne, and surgical wounds. It seems to modulate the immune system and consequently has been purported to have antiviral, antibacterial, and anticancer properties.

Zinc deficiency sometimes occurs due to an inadequate diet or one that includes a high content of phytic acid, fiber, phosphate, calcium, or copper, all of which diminish absorption.

Zinc telluride is a semiconductive material that has been found to become photorefractive when it is suitably doped with vanadium or with manganese and vanadium. The combination of photorefractivity and semiconductivity makes this material attractive for use in a variety of applications, including optical power limiting (for shielding eyes or delicate sensors against intense illumination), holographic interferometry, providing reconfigurable optical interconnections for optical computing and optical communication, and correcting for optical distortions and combining laser powers via phase conjugation. In comparison with other important photorefractive materials based on III-V and II-VI binary compounds, ZnTe/V offers superior photorefractive performance at wavelengths from 0.6 to 1.3 μm .

Undoped or doped ZnTe can be grown by physical vapor transport in a closed ampoule.

Experiments were performed to investigate the utility of ZnTe/V /Mn for real-time resonant holographic interferometry. These experiments involved, variously, two- or four-wave mixing, using pulsed dye or continuous-wave helium-neon or diode lasers. Holographic image transfer and two-wavelength resonant holographic interferometry were demonstrated; in particular, a ZnTe/V/Mn crystal was used in a demonstration of resonant holographic interferometric spectroscopy, which is a technique for obtaining chemical-species-specific interferograms by recording two holograms simultaneously at two slightly different wavelengths near an absorption spectral peak of the species in question.

A vehicle (AT-1) was fitted with zinc-air batteries and ran for 1043 miles at 20–25 mph. The batteries consisted of 180 zinc-air cells weighing 1.9 kg and outputting 1.1 V each. On the record run, they delivered 76 kWh of power with 10% remaining, compared to the total capacity of the Saturn EV-1 of 16.2 kWh from a lead-acid battery pack that weighs 50% more than that in the AT-1. A unique aspect of the batteries is that they are intended to be physically swapped from the vehicle in minutes instead of recharged onboard for hours.

Intended for emerging market countries, the AT-1 is a five-passenger utility vehicle that can be configured in a variety of ways. Weighing 635.6 kg, it can carry a 590.2 kg load. Depending on motor, it has a top speed of 40–70 mph.

Although zinc-air batteries offer about four times the energy density of lead-acid, their weakness is specific power. It should be noted that this could be addressed by combining zinc-air batteries with other batteries or an ultracapacitor. As vehicles based on crude oil lose their selling position, zinc-air fuel cells are expected to capture a substantial part of the market.

Z

Alloys

Alloys of zinc are mostly used for die castings for decorative parts and for functional parts where the load-bearing and shock requirements are relatively low. Because the zinc alloys can be cast easily in high-speed machines, producing parts that weigh less than brass and have high accuracy and smooth surfaces that require minimum machining and finishing, they are widely used for such parts as handles and for gears, levers, pawls, and other small parts. Zinc alloys for sheet contain only small amounts of alloying elements, with 90%–98% zinc, and the sheet is generally referred to simply as zinc or by a trade name. The modified zinc sheet is used for stamped, drawn, or spun parts for costume jewelry and electronics and contains up to 1.5% copper and 0.5% titanium. The titanium raises the recrystallization temperature, permitting heat treatment without coarse grain formation.

Hartzink had 5% iron and 2%–3% lead, but iron forms various chemical compounds with zinc, and the alloy is hard and brittle. Copper reduces the brittleness. *Germania*-bearing bronze contained 1% iron, 10% tin, about 5% each of copper and lead, and the balance zinc. The *Fenton* alloy had 14% tin, 6% copper, and 80% zinc, and the *Ehrhard*-bearing metal contained 2.5% aluminum, 10% copper, 1% lead, and a small amount of tin to form copper–tin crystals. *Binding* metal, for wire-rope slings, has about 2.8% tin, 3.7% antimony, and the balance zinc. Pattern metal, for casting gates of small patterns, was almost any brass with more zinc and some lead added but is now standard die-casting metal.

Zinc also is commonly used in varying degrees as an alloy component with other base metals, such as copper, aluminum, and magnesium. A familiar example of the latter is the association of varying amounts of zinc (up to 45%) with copper to produce brass.

Zinc alloys are commonly used for die castings, and the zinc used is high-purity zinc known as special high-grade zinc. The ASTM AG40A and SAE 903 are the most widely used; others include AC41A (SAE 925), Alloy 7, and ILZRO 16. All typically contain about 4% aluminum, small amounts of copper, and very small amounts of magnesium. AG40A has a density of 6.6 mg/m³, an electrical conductivity of 27% that of copper, a thermal conductivity of 113 W/m·K, an ultimate tensile strength of 283 MPa, and a hardness of Brinell 82. AC41A is stronger (331 MPa) and harder (Brinell 91), a trifle less electrically and heat conductive, and similar in density. The alloys have much greater unnotched Charpy impact strength than either die-cast aluminum or magnesium alloys, but are not especially heat resistant, losing about one-third of their strength at temperatures above about 93°C. Both alloys have found wide use for auto and appliance parts, especially chromium-plated parts, as well as for office equipment parts, hardware, locks, toys, and novelties. Alloy 7 is noted primarily for its better castability and the smoother surface finish it provides. It is as strong as AG40A, although slightly less hard and more ductile. ILZRO 16 is not nearly as strong (228 MPa), but more creep-resistant at room and elevated temperatures.

Casting Alloys

Zinc-casting alloys can be grouped into two general categories: standard zinc die-casting alloys and the newer zinc–aluminum casting alloys.

Standard Die-Casting Alloys

For pressure die casting, the established zinc alloys are the No. 3, 5, and 7 *Zamak* alloys. As die castings, they have good general-purpose tensile properties and can be cast in thin sections and with good dimensional accuracy. The alloys are often selected for plated or highly decorative applications because of their excellent

finishing characteristics. Three major end-use areas for zinc die-cast components are automotive, building hardware, and electrical.

Zamak alloys contain approximately 4% aluminum with low percentages of magnesium, copper, and sometimes nickel. Impurities such as tin, lead, and cadmium are carefully controlled. These alloys are not recommended for gravity casting. They are cast by the hot-chamber die-casting process, which is different from, and more efficient than, the cold-chamber die-casting process commonly used for aluminum. In addition, a specialized process is used for efficient production of miniature die-cast components, using these alloys as well as ZA-8.

Typical tolerances of zinc die-cast parts are ± 0.0015 in./in., for the first inch with an additional ± 0.002 in./in. for larger parts. New zinc-casting technology allows for thin walls down to 0.025 in. (0.6 mm), improved internal soundness, and surface finishes that range typically from 32 to 64 root mean square.

Part dimensions change slightly when zinc die castings are aged. *Zamak* alloys No. 3 and 7 can shrink about 0.0007 in./in. after several weeks at room temperature. Alloy No. 5 responds similarly, but total shrinkage can be 0.0009–0.0024 in./in., followed by expansion of 0.0020 in./in. over a period of years. When it is necessary to bring these changes to completion within a short time after casting, a stabilizing treatment of 4–6 h at 100°C is recommended.

ZA-Casting Alloys

Designated as ZA-8, ZA-12, and ZA-27 (the numerical suffix represents the approximate percent by weight of aluminum), the high-aluminum alloys differ radically from the standard *Zamak* alloys in composition, properties, and castability. Although the ZA alloys were first introduced for gravity casting (sand and permanent mold), they have expanded into pressure die castings as well as a new, precision graphite-mold process. **Important:** Alloys ZA-12 and ZA-27 must be cold-chamber die cast; alloy ZA-8 is hot-chamber castable.

Gravity casting into low-cost graphite permanent molds provides high-quality ZA castings with excellent precision, eliminating much machining. It is particularly competitive for production quantities of 500–15,000 parts/year, where die casting or plastic injection molding would be prohibited because of tooling costs.

ZA alloys combine high strength and hardness (up to 480 MPa and 120 Bhn), good machineability with good bearing properties, and wear resistance often superior to standard bronze alloys. ZA castings are now competing with cast iron, bronze, and aluminum because of various property and processing advantages.

Of the three alloys, ZA-12 is preferred for most applications, and particularly for gravity casting. However, ZA-27 offers the highest mechanical properties regardless of casting method. Both are excellent bearing materials. ZA-8, on the other hand, gives the best plating characteristics. Because of its hot-chamber die castability and high mechanical properties, ZA-8 is also used for high-performance applications where standard zinc alloys can be marginal. All ZA alloys offer superior creep resistance and performance at elevated temperatures compared with the *Zamak* alloys.

The most recent casting alloys discussed earlier are three high-aluminum zinc-casting alloys for sand and permanent-mold casting: ZA-8, ZA-12, and ZA-27; the numerals in the designations indicate approximate aluminum content. They also contain more copper than AG40A and AC41A, from 0.5% to 1.2% in ZA-12 to 2% to 2.5% in ZA-27, and a bit less magnesium. As sand cast, ultimate tensile strengths range from 248 to 276 MPa for ZA-8 and 400 to 441 MPa for ZA-27. Unlike the common die-casting alloys, the ZA alloys also exhibit clearly defined tensile yield strengths: from 193 MPa minimum for sand-cast ZA-8 to 365 MPa for sand-cast ZA-27.

Tensile modulus is roughly 83×10^3 MPa. Also, because of their greater aluminum content, they are lighter in weight than the die-casting alloys.

Wrought Alloys

Wrought zinc alloys are available in rolled sheet, strip, foil, and as drawn rod or wire. With controlled rolling, zinc alloys can be tailored to meet a wide range of hardness, luster, and ductility requirements. Rolled zinc can be worked by common fabricating methods, and then polished, lacquered, painted, or plated.

When zinc alloys are formed in progressive presses, as in battery shell manufacture, they are self-annealing. After successive forming operations in nonprogressive presses, however, the alloys work-harden and break. This can be overcome, in copper-free alloys, by intermediate annealing for 5 min in boiling water to which 20% glycerin has been added. Copper-bearing alloys should be heated 5–10 min at 177°C. The copper/titanium-containing alloy should be held at 199°C for about 15 min to bring about recrystallization. Excessive exposure to higher temperature should be avoided, however, to prevent grain growth, cleavage cracks, and property deterioration.

Highly workable and highly forgeable wrought-zinc alloys containing titanium, aluminum, lead, cadmium, copper, or iron in various quantities are easily machined. Forged or extruded parts are free from porosity and have good detail.

Other Alloys

Manganese–zinc alloys with up to 25% manganese, for high-strength extrusions and forgings, are really 60–40 brass with part of the copper replaced by an equal amount of manganese and are classed with manganese bronze. They have a bright white color and are corrosion resistant. Zam metal, for zinc-plating anodes, is zinc with small percentages of aluminum and mercury to stabilize against acid attack. Zinc solders are used for joining aluminum. The tin–zinc solders have 70%–80% tin, about 1.5% aluminum, and the balance zinc. The working range is 260°C–310°C. Zinc–cadmium solder has about 60% zinc and 40% cadmium. The pasty range is between 266°C and 315°C.

A group of wrought alloys, called superplastic zinc alloys, have elongations of up to 2500% in the annealed condition. These alloys contain about 22% aluminum. One grade can be annealed and air-cooled two strains of 489 MPa. Parts of these alloys have been produced by vacuum forming and by a compression molding technique similar to forging but requiring lower pressures.

Chemicals

With the exception of the oxide, the quantities of zinc compounds consumed are not large compared with many other metals, but zinc chemicals have a very wide range of use; they are essential in almost all industries and for the maintenance of animal and vegetable life. Zinc is a complex element and can provide some unusual conditions and alloys and chemicals.

Zinc Oxide

Zinc oxide, ZnO, is a white, water-insoluble, refractory powder melting at about 1975°C, with a specific gravity of 5.66. It is much used as a pigment and accelerator in paints and rubbers. Its high refractive index, about 2.01, absorption of ultraviolet light, and fine particle size give high hiding power in paints and make it also useful in such products as cosmetic creams to protect against sunburn. Commercial zinc oxide is always white and in the paint industry is

called *zinc white* and *Chinese white*. But with a small excess of zinc atoms in the crystals, obtained by heat treatment, the color is brown to red.

In paints, zinc oxide is not as whitening as lithopone, but it resists the action of ultraviolet rays and is not affected by sulfur atmospheres, and is thus valued in outside paints. Leaded zinc oxide, consisting of zinc oxide and basic lead sulfate, is used in paints, but for use in rubber, the oxide must be free of lead. The lead-free variety is also called *French process zinc oxide*. In insulating compounds, zinc oxide improves electrical resistance. In paper coatings, it gives opacity and improves the finish. Zinc-white paste for paint mixing usually has 90% oxide and 10% oil. Zinc oxide stabilizers, composed of zinc oxides and other chemicals, can be added to plastic molding compounds to reduce the deteriorating effects of sunlight and other types of degrading atmospheres.

The rubber industry is the largest consumer of zinc oxide, accounting for more than 50% of the market. Zinc oxide is most effective as an activator of accelerators in the vulcanization process.

The chemical industry has been opening new markets for zinc oxide. Examples are lubricating oil additives, water treatment, and catalysts. For photocopying, photoconductivity is a unique electronic property of zinc oxide.

In the ceramic industry, zinc oxide is used in the manufacture of glasses, glazes, frits, porcelain enamels, and magnetic ferrites. Here, the largest consuming plants are in the tile industry.

One ceramic grade of zinc oxide has these properties: specific gravity 5.6, apparent density 1201 kg/m³, and weight 5595.5 kg/m³. Typical chemical analysis: 99.5% ZnO, 0.05% Pb, 0.02% Fe, 0.01% Cd, 0.02% S (total), 0.10% HCl (insoluble), and 5 ppm magnetic iron.

In glass, zinc oxide reduces the coefficient of thermal expansion, thus making possible the production of glass products of high resistance to thermal shock. It imparts high brilliance of luster and high stability against deformation under stress. As a replacement flux for the more soluble alkali constituents, it provides a viscosity curve of lower slope. Specific heat is decreased and conductivity increased by the substitution of zinc oxide for BaO and PbO.

A 1% addition of zinc oxide to tank window glass lowers the devitrification temperature and improves chemical resistivity while maintaining good workability for drawing. It is used consistently in high-grade fluoride opal glass in which it greatly increases opacity, whiteness, and luster by inducing precipitation of fluoride crystals of optimum number and size. Apparently, zinc oxide makes its contribution to opacity through reduction of the primary opacifiers. It is used in optical glasses of high barium content to reduce the tendency to crystallize on cooling. The resistance of phosphate glasses to chemical attack is improved by the presence of zinc oxide. About 10% zinc oxide assists in the development of the characteristic color of cadmium sulfoselenide ruby glass, although its exact function is obscure.

Zinc oxide is used in many types of glazes, its function varying according to the particular composition in which it is included. In general, it provides fluxing power, reduction of expansion, prevention of crazing, greater gloss and whiteness, the favorable effect on elasticity, increased maturing range, increased brilliance of colors, and correction of eggshell finish. It is useful in preventing volatilization of lead by partial substitution for CaO, as high CaO tends to satisfy SiO₂, leaving PbO in a more volatile form.

In *Bristol* glazes for earthenware products, zinc oxide in combination with alumina produces opacity and whiteness to a fair degree, provided that the lime content is low. The use of zinc oxide in wall tile glazes is very general; zinc oxide content of certain types is 10% or more. Small amounts are used in gloss or bright tile, where its higher percentages are used where it is desired to develop a highly pleasing matte finish.

Z

Zinc oxide is commonly used in dry-process cast-iron porcelain enamels in amounts of 0.5%–1%–14%. In general, low lead content implies high zinc, and vice versa. Its specific functions are to increase fusibility, improve luster, contribute to opacity and whiteness, reduce expansion, and increase extensibility. It is probably a little stronger as a flux than is lime but does not produce the sudden fluidity characteristics of lime.

Of great benefit to producers of cast-iron enamels is the relative nontoxicity of zinc oxide.

A recent use for zinc oxide is its application to the manufacture of magnetic ferrites, which have been developed over the past 35–40 years. They usually are composed of ferric oxide in combination with zinc oxide (of high chemical purity) and any one or more of several other oxides of bivalent metals. The amount of zinc oxide used varies from 10% to 35%, depending on the characteristics desired in the finished magnetic ferrite. With their prime properties of high permeability and low hysteresis, they are used in the field of electronics for such devices as high-frequency transformer cores for television receivers.

Zinc oxide crystals are used for transducers and other piezoelectric devices. The crystals are hexagonal and are effective at elevated temperatures, as the crystal has no phase change up to its disassociation point. The resistivity range is $0.5\text{--}10\ \Omega\cdot\text{cm}$. Normally recognized as an *n*-type semiconductor, it has a resistivity less than $103\ \Omega\cdot\text{cm}$. When doped with lithium, resistivity rises to $1012\ \Omega\cdot\text{cm}$ and it exhibits piezoelectricity about four times that of quartz.

Zinc oxide has luminescent and light-sensitive properties that are utilized in phosphors and ferrites. But the oxygen-dominated zinc phosphors used for radar and television are modifications of zinc sulfide phosphors.

Zinc sulfide phosphors, which produce luminescence by exposure to light, are made with zinc sulfide mixed with about 2% sodium chloride and 0.005% copper, manganese, or other activator and fired in a nonoxidizing atmosphere. The cubic crystal structure of zinc sulfide changes to a stable hexagonal structure at 1020°C , but both forms have the phosphor properties. Thin films and crystals of zinc selenide with purities of 99.999% are used for photo and electroluminescent devices. Zinc sulfide, a white powder, is also used as a paint pigment and for whitening rubber and for paper coating. *Cryptone* is zinc sulfide for pigment use at various grades, some grades containing barium sulfate, calcium sulfide, or titanium dioxide.

Zinc Blend

Zinc sulfide, ZnS, ore.

Zinc Coating

See *galvanizing*.

Zinc Chromate

An orange-colored constituent of some primer paints. It is not simply a pigment but provides some sacrificial cathodic protection particularly for aluminum in marine environments.

Zinc (Based) Die-Casting Alloy

Various alloys, principally zinc but with additions of aluminum, typically about 4%, possibly with small amounts of copper, lead,

cadmium, etc. These materials have relatively low melting points and provide castings with good finish and detail.

Zinc Ores

The metal zinc is obtained from a large number of ores, but the average zinc content of the ores in the United States is only about 3% so that they are concentrated to contain 35%–65% before treatment. The sulfide ores are marketed on the basis of 60% zinc content and the oxide ores on the basis of 40% zinc content. *Sphalerite*, or *zinc blende*, is the most important and has been found in quantities in Missouri and surrounding states and in Europe. Sphalerite is a zinc sulfide, ZnS, containing theoretically 67% zinc. It has a massive crystalline or granular structure and a Mohs hardness of about 4. When pure, its color is white; it colors yellow, brown, green, to black with impurities.

Calamine is found in New Jersey, Pennsylvania, Missouri, and Europe. It is the ore that was formally mixed directly with copper for making brass. The ore usually contains only about 3% zinc and is concentrated to 35%–45%, and then roasted and distilled. Calamine is zinc silicate. It is a mineral occurring in crystal groups of a vitreous luster, and it may be white, greenish, yellow, or brown. The specific gravity is 3.4 and Mohs hardness 4.5–5. It occurs in Arkansas with *smithsonite*, a zinc carbonate ore. *Franklinite* is an ore of both the metals zinc and manganese.

The ore *zincite* is used chiefly for the production of the zinc oxide known as zinc white employed as a pigment. Zincite has the composition ZnO, containing theoretically 80.3% zinc. The mineral has usually a massive granular structure with a deep-red to orange streaked color. It may be translucent or almost opaque. Deep-red specimens from the workings at Franklin, New Jersey, are cut into gemstones for costume jewelry. *Willemite* is an anhydrous silicate containing theoretically 58.5% zinc. When manganese replaces part of the zinc, the ore is called *troostite*. It is in hexagonal prisms of white, yellow, green, or blue; manganese makes it apple green, brown, or red. The specific gravity is about 4 and Mohs hardness 5.5. The crushed ore is used in making fluorescent glass. The ore is widely dispersed in the United States.

Zinc Tinsel

An alloy of about 60% zinc and 40% lead, which is bright and reasonably tarnish resistant for decorative applications.

Zinc White

Zinc oxide, ZnO.

Zinc Worms

Surface imperfections, characteristic of high-zinc brass castings, which occur when zinc vapor condenses at the mold/metal interface, where it is oxidized and then becomes entrapped in the solidifying metals.

Zircon

Zircon, a mineral with the idealized composition ZrSiO_4 , is one of the chief sources of the element zirconium. Trace amounts of uranium and thorium are often present and in general may then be partly or entirely metamict. The name “cyrtolite” is applied to an

altered type of zircon. Structurally, zircon is a nesosilicate, with isolated SiO_4 groups.

Zircon is tetragonal in crystallization. It often occurs as well-formed crystals, which commonly are square prisms terminated by a low pyramid. The color is variable, usually brown to reddish brown, but also colorless, pale yellowish, green, or blue. The transparent colorless or tinted varieties are popular gemstones. Hardness is 7 1/2 on Mohs scale; specific gravity is 4.7, decreasing in metamict types.

Because of its chemical and physical stability, zircon resists weathering and accumulates in residual deposits and in beach and river sands.

Other properties include specific heat of 0.55 J/g/°C. It is chemically inert and stable in very high temperatures (liquidus > 2205°C). Zircon has excellent thermal properties, and its thermal conductivity is 14.5 Btu/ft²/h/°F/in., and coefficient of thermal expansion is 1.4×10^{-6} .

The extremely high thermal conductivity and chilling action of zircon make it very useful in controlling directional solidification and shrinkage in heavy-metal sections.

Uses

Zircon sand is used as refractory bedding material for heat-treating metal parts. It is used as a sealing medium for prevention of atmospheric leaks around doors and parts of heat-treating furnaces. Also, it is a high-quality, uniform sandblasting medium for metal preparation prior to plating, enameling, or buffing. The heavy, rounded grains give consistent peening without stray digs or gouges to mar the finish. The tough, resilient grains resist breakdown and loss.

Zirconia (Zirconium Oxide)

Zirconium oxide, ZrO_2 , is a white crystalline powder with a specific gravity of 5.7, hardness 6.5, and refractive index 2.2. When pure, its melting point is about 2760°C, and it is one of the most refractory of the ceramics. It is produced by reacting zircon sand and dolomite at 1371°C and leaching out the silicates. The material is used as fused or sintered ceramics and for crucibles and furnace bricks. From 4.5% to 6% of CaO or other oxide is added to convert the unstable monoclinic crystal to the stable cubic form with a lowered melting point.

Zirconia is produced from the zirconium ores known as zircon and *baddeleyite*. The latter is a natural zirconium oxide. It is also called *zirkite* and *brazilite*. Zircon is zirconium silicate and comes chiefly from the beach sands. The sands are also called *zirkelite* and *zirconite*, or merely zircon sand. The white zircon sand has a zirconia content of 62% and contains less than 1% iron.

Uses

Fused zirconia, used as a refractory ceramic, has a melting point of 2549°C and a usable temperature up to 2454°C. The *zinnorite* fused zirconia is a powder that contains less than 0.8% silica and has a melting point of 2704°C. A sintered zirconia can have a density of 5.4, a tensile strength of 82 MPa, a compressive strength of 1378 MPa, and a Knoop hardness of 1100. *Zircoa B* is stabilized cubic zirconia used for making ceramics. *Zircoa A* is the pure monoclinic zirconia used as a pigment, as a catalyst in glass, and as an opacifier in ceramic coatings.

As an opacifier, zirconium compounds are used in glazes and porcelain enamels. Zirconium dioxide is an important constituent

of ceramic colors and an important component of lead–zirconate–titanate electronic ceramics.

Pure zirconia also is used as an additive to enhance the properties of other oxide refractories. It is particularly advantageous when added to high-fired magnesia bodies and alumina bodies. It promotes sinterability and, with alumina, contributes to abrasive characteristics.

Zirconia brick for lining electric furnaces has no more than 94% zirconia, with up to 5% CaO as a stabilizer, and some silica. It melts at about 2371°C but softens at about 1982°C. The IBC 4200 brick is zirconia with calcium and hafnium oxides for stabilizing. It withstands temperatures up to 2316°C in oxidizing atmospheres and up to 1849°C in reducing atmospheres. Zirconia foam is marketed in bricks and shapes for thermal insulation. With a porosity of 75%, it has a flexural strength above 3 MPa and a compressive strength above 0.7 MPa. For use in crucibles, zirconia is insoluble in most metals except the alkali metals and titanium. It is resistant to most oxides; but with silicate, it forms ZrSiO_4 ; and with titania, it forms ZrTiO_4 . Because structural disintegration of zirconia refractories comes from crystal alteration, the phase changes are important considerations. The monoclinic material, with a specific gravity of 5.7, is stable up to 1010°C and then inverts to the tetragonal crystal with a specific gravity of 6.1 and a volume change of 7%. It reverts when the temperature again drops below 1010°C. The cubic material, with a specific gravity of 5.55, is stable at all temperatures to the melting point, which is not above 2649°C because of the contained stabilizers. A lime-stabilized zirconia refractory with the tensile strength of 138 MPa has a tensile strength of 68 MPa at 1299°C.

Stabilized zirconia has a very low coefficient of expansion, and white-hot parts can be plunged into cold water without breaking. The thermal conductivity is only about one-third that of magnesia. It is also resistant to acids and alkalies and is a good electrical insulator.

To prepare useful formed products from zirconium oxide, stabilizing agent such as lime, yttrium, or magnesia must be added to the zirconia, preferably during fusion, to convert the zirconia to the cubic form. Most commercial stabilized zirconia powders or products contain CaO as the stabilizing agent. The stabilized cubic form of zirconia undergoes no inversion during heating and cooling.

Stabilized zirconia refractories are used where extremely high temperatures are required. Above 1649°C, in contact with carbon, zirconia is converted to zirconium carbide.

Zirconia is of much interest as a construction material for nuclear energy applications because of its refractoriness, corrosion resistance, and low nuclear cross section. However, zirconia normally contains about 2% hafnia, which has a high nuclear cross section. The hafnia must be removed before the zirconia can be used in nuclear applications.

Forms

Zirconia is available in several distinct types. The most widely used form is stabilized in cubic crystal form by a small lime addition. This variety is essential to the fabrication of shapes because the so-called unstabilized monoclinic zirconia undergoes a crystalline inversion on heating, which is accompanied by a disruptive volume change.

Zirconium is not wetted by many metals and is therefore an excellent crucible material when slag is absent. It has been used very successfully for melting alloy steels and the noble metals. Zirconia refractories are rapidly finding application as setter plates for ferrite and titanate manufacture, and as matrix elements and wind tunnel liners for the aerospace industry.

Z

Other Types

Toughening mechanisms, by which a crack in a ceramic can be arrested, complement processing techniques that seek to eliminate crack-initiating imperfections. Transformation toughening relies on a change in crystal structure (from tetragonal to monoclinic) that zirconia or zirconium dioxide (ZrO_2) grains undergo when they are subjected to stresses at a crack tip. Because the monoclinic grains have a slightly larger volume, they can “squeeze” a crack shut as of calcium and they expand in the course of transformation. Because of the transformation toughening abilities of ZrO_2 , which impart higher fracture toughness, research interest in engine applications has been high. In order for ZrO_2 to be used in high-temperature, structural applications, it must be stabilized or partially stabilized to prevent a monoclinic–tetragonal phase change. Stabilization involves the addition of calcia, magnesia, or yttria followed by some form of heat treatment. Partially stabilized zirconia (PSZ) ceramic, the toughest known ceramic, has been investigated for diesel-engine applications.

PSZ is a transformation-toughened material consisting of a cubic zirconia matrix with 20–50 vol% free tetragonal zirconia added in the matrix. The material is converted into the stabilized cubic crystal structure using oxide stabilizers (magnesia, calcia, yttria). The conversion is accomplished by sintering the doped zirconia at 1700°C. Magnesia-stabilized zirconia exhibits serrated plastic flow during compression at room temperature. The flow stress is strain rate sensitive. Several different grades are available for commercial use, and the properties of the material can be tailored to fit many applications.

One typical PSZ used for applications requiring maximum thermal shock resistance has a four-point bend strength of 600 MPa; PSZ is used experimentally as heat engine components, such as cylinder liners, piston caps, and valve seats. Vanadium impurities from fuel oil can cause zirconia destabilization, and sodium, magnesium, and sulfur impurities can cause yttria to disassociate from yttria-stabilized zirconia. Another area of interest for PSZ is in bioceramics, where it has use in surgical implants.

A new zirconia ceramic being developed, tetragonal zirconia polycrystal (TZP) doped with Y_2O_3 , has the most impressive room-temperature mechanical properties of any zirconia ceramic. The commercial applications of TZP zirconia include scissors with TZP blades suitable for industrial use for cutting tough fiber fabrics, for example, Kevlar, cables, and ceramic scalpels for surgical applications. One unique application is fish knives. The knife blades are Y-TZP and can be used when the delicate taste of raw fish would be tainted by slicing with knives with metal blades.

Another zirconia ceramic-developed material is zirconia-toughened alumina (ZTA). ZTA is a composite polycrystalline ceramic containing ZrO_2 , as a dispersed phase (typically ~15 vol%). Close control of initial starting powder sizes and sintering schedules is thus necessary to attain the desired ZrO_2 particle dimensions in the finished ceramic. Hence, the mechanical properties of the composite ZTA ceramics limit current commercial applications to cutting tools and ceramic scissors.

PSZ is also finding application in the transformation toughening of metals used in the glass industry as orifices for glass fiber drawing. This material is termed zirconia grain-stabilized platinum.

Clear zircon crystals are valued as gemstones because the high refractive index gives great brilliance.

Zirconia fiber, used for high-temperature textiles, is produced from zirconia with about 5% lime for stabilization. The fiber is polycrystalline, has a melting point of 2593°C, and will withstand continuous temperatures above 1649°C. These fibers are as small as 3–10 μm and are made into fabrics for filter and fuel cell use.

Zirconia fabrics are woven, knitted, or felted of short-length fibers and are flexible. Ultratemp adhesive, for high-heat applications, is zirconia powder in solution. At 593°C, it adheres strongly to metals and will withstand temperatures up to 2427°C. *Zircar* is zirconia fiber compressed into sheets to a density of 320 kg/m^3 . It will withstand temperatures up to 2482°C and has low thermal conductivity. It is used for insulation and for high-temperature filtering.

Zirconium and Alloys

A silvery-white metal, zirconium (Zr), has a specific gravity of 6.5 and a melting point of about 1850°C. It is more abundant than nickel, but is difficult to reduce to metallic form as it combines easily with oxygen, nitrogen, carbon, and silicon. The metal is obtained from zircon sand by reacting with carbon and then converting to the tetrachloride, which is reduced to a sponge metal for the further production of shapes. The ordinary sponge zirconium contains about 2.5% hafnium, which is closely related and difficult to separate. The commercial metal usually contains hafnium, but reactor-grade zirconium, for use in atomic work, is hafnium-free.

Commercially pure zirconium is not a high-strength metal, with the tensile strength of about 220 MPa, elongation 40%, and Brinell hardness 30, or about the same physical properties as pure iron. But it is valued for atomic construction purposes because of its low neutron capture cross section, thermal stability, and corrosion resistance. It is employed mostly in the form of alloys but may be had in 99.99% pure single-crystal rods, sheets, foil, and wire for superconductors, surgical implants, and vacuum-tube parts. The neutron cross section of zirconium is 0.18 barn, compared with 2.4 for iron and 4.5 for nickel. The cold-worked metal, with 50% reduction, has a tensile strength of about 545 MPa, with an elongation of 18% and hardness of Brinell 95. The unalloyed metal is difficult to roll and is usually worked at temperatures up to 482°C. Although nontoxic, the metal is pyrophoric because of its heat-generating reaction with oxygen, necessitating special precautions in handling powder and fine chips resulting from machining operations.

The metal has a close-packed hexagonal crystal structure, which changes at 862°C to a body-centered cubic structure that is stable to the melting point. At 300°C–400°C, the metal absorbs hydrogen rapidly, and above 200°C, it picks up oxygen. At about 400°C, it takes up nitrogen, and at 800°C, the absorption is rapid, increasing the volume and embrittling the metal.

The metal is not attacked by nitric (except red fuming nitric), sulfuric, or hydrochloric acid, but is dissolved by hydrofluoric acid. Zirconium powder is very reactive, and for making sintered metals, it is usually marketed as zirconium hydride, ZrH_2 , containing about 2% hydrogen, which is driven off when the powder is heated to 300°C. For making sintered parts, alloyed powders are also used. Zirconium copper (containing 35% zirconium), zirconium nickel (with 35%–50% zirconium), and zirconium cobalt (with 50% zirconium) are marketed as powders of 200–300 mesh.

Properties

In addition to resisting HCl at all concentrations and at temperatures above the boiling temperature, zirconium and its alloys also have excellent resistance in sulfuric acid at temperatures above boiling and concentrations to 70%. Corrosion rate in nitric acid is less than 1 mil/year at temperatures above boiling and concentrations to 90%. The metals also resist most organics such as acetic acid and acetic anhydride as well as citric, lactic, tartaric, oxalic, tannic, and chlorinated organic acids.

Relatively few metals beside zirconium can be used in chemical processes requiring alternate contact with strong acids and alkalis. However, zirconium has no resistance to hydrofluoric acid and is rapidly attacked, even at very low concentrations.

Uses

Small amounts of zirconium are used in many steels. It is a powerful deoxidizer, removes the nitrogen, and combines with the sulfur, reducing hot shortness and giving ductility. Zirconium steels with small amounts of residual zirconium have a fine grain and are shock resistant and fatigue resistant. In amounts above 0.15%, the zirconium form zirconium sulfide and improves the coating quality of the steel.

A noncrystalline metal that reportedly has twice the strength of steel and titanium has been developed. The material, known as *Vitreloy*, is an alloy composed of 61% zirconium, 12% titanium, 12% copper, 11% nickel, and 3% beryllium. Its yield strengths is 1900 MPa, compared with 800 MPa for titanium alloy, Ti-6%Al-4%V, and 850 MPa for cast stainless steel.

Fracture toughness is said to be 55 MPa m^{1/2}, the same as high-strength steel but half that of titanium. Its resistance to permanent deformation is said to be two to three times higher than that of conventional metals. The density of *Vitreloy* is 6.1 g/cm³ between cast titanium at 4.5 g/cm³ and cast stainless steel at 7.8 g/cm³. The material is particularly recommended for aerospace applications because of its surface hardness of 50 HRC. Cast titanium and steel are both tested at 30 HRC.

The beneficial properties of the alloy are ascribed to its noncrystalline structure. Because there are no patterns or grains within the structure, weak areas caused by grain boundaries are eliminated.

An advanced machinable ceramic that may be used to produce thermal shock-resistant components for aerospace, automotive, electrical, heat treating, metallurgical, petrochemical, and plastics applications up to 1550°C has been introduced. The new material (*Aremcolox*TM 502-1550) is based on the zirconium phosphate system (Ba_{1+x}Zr₄P_{6-2x}Si_{2x}O₂₄) and is especially unique because of its low coefficient of thermal expansion (CTE) of 0.5 × 10⁻⁶ in./in. °F. This characteristic sets the material apart from standard ceramic materials such as alumina and zirconia, which have CTEs of 4.0 × 10⁻⁶ and 2.5 × 10⁻⁶, respectively.

A low CTE ensures that as a component is thermally cycled, the mechanical stress induced through expansion and contraction does not cause the part to crack. This feature enables engineers to adapt the material to high thermal shock applications, such as combustion and heater systems, that were not previously feasible.

Additional properties and applications of the machinable ceramic include their use as molds, optical stands, microwave housings, engine parts, and applications in which high mechanical strength, hardness, and low porosity are required. A low-density version of the material (502-1550 LD) is recommended for use as brazing fixtures, induction heating liners, rocket nozzles, and high-temperature gauges, tooling, and structures. The material is easily machined using carbide tooling, and no postfiring is required.

Alloys

Zirconium alloys generally have only small amounts of alloying elements to add strength and resist hydrogen pickup. Zircaloy 2, for reactor structural parts, has 1.5% tin, 0.12% iron, 0.10% chromium, 0.05% nickel, and the balance zirconium. Tensile strength is 468 MPa, elongation 37%, and hardness Rockwell B89; at 316°C, it retains its strength of 206 MPa.

Zirconium alloys can be machined by conventional methods, but they have a tendency to gall and work-harden during machining. Consequently, tools with higher than normal clearance angles are needed to penetrate previously work-hardened surfaces. Results can be satisfactory, however, with cemented carbide or high-speed steel tools. Carbide tools usually provide better finishes and higher productivity.

Mill products are available in four principal grades: 702, 704, 705, and 706. These metals can be formed, bent, and punched on standard shop equipment with a few modifications and special techniques. Grades 702 (unalloyed) and 704 (Zr-Sn-Cr-Fe alloy) sheet and strip can be bent on conventional press brake or roll-forming equipment to a 5*t* bend radius at room temperature and to 3*t* at 200°C. Grades 705 and 706 (Zr-Cb alloys) can be bent to 3*t* and 2.5*t* radius at room temperature and to about 1.5*t* at 200°C.

Small amounts of zirconium in copper give age hardening and increase the tensile strength. Copper alloys containing even small amounts of zirconium are called zirconium bronze. They pour more easily than bronzes with titanium, and they have good electric conductivity. Zirconium copper master alloy for adding zirconium to brasses and bronzes is marketed in grades with 12.5% and 35% zirconium. A nickel-zirconium master alloy has 40%–50% nickel, 25%–30% zirconium, 10% aluminum, and up to 10% silicon and 5% iron. Zirconium-ferrosilicon, for alloying with steel, contains 9%–12% zirconium, 40%–47% silicon, 40%–45% iron, and 0.20% max carbon, but other compositions are available for special uses. SMZ alloy (silicon, manganese, and zirconium), for making high-strength cast irons without leaving residual zirconium in the iron, has about 75% silicon, 7% manganese, 7% zirconium, and the balance iron. A typical zirconium copper for electrical use is *Amzirc*. It is oxygen-free copper with only 0.15% of zirconium added. At 400°C, it has a conductivity of 37% IACS, a tensile strength of 358 MPa, and an elongation of 9%. The softening temperature is 580°C.

Zirconium alloys with high zirconium content have few uses except for atomic applications. Zircaloy tubing is used to contain the uranium oxide fuel pellets in reactors because the zirconium does not have grain growth and deterioration from radiation. Zirconia ceramics are valued for electrical and high-temperature parts and refractory coatings. Zirconium oxide powder, for flame-sprayed coatings, comes in either hexagonal or cubic crystal forms. Zirconium silicate, ZrSi₂, comes as a tetragonal crystal powder. Its melting point is about 1649°C and hardness about 1000 Knoop.

Zirconium Beryllides

Intermetallic compounds, ZrBe₁₃ and Zr₂Be₁₇, have good strengths at elevated temperatures. ZrBe₁₃ is cubic, density 2.72 g/cm³, and melting point 1925°C; Zr₂Be₁₇ is hexagonal, density 3.08 g/cm³, and melting point 1983°C; parts can be formed by all ceramic-forming methods plus flame and plasma-arc spraying. Materials are subject to safety requirements for all beryllium compounds.

These intermetallics, because of their greater densities (BeO = 1.85 g/cm³), contain more beryllium atoms per unit volume than beryllia, a decided advantage for compact, beryllium-moderated nuclear reactors.

Zirconium Carbide

Zirconium carbide, ZrC₂, is produced by heating zirconia with carbon at about 2000°C. The cubic crystalline powder has a hardness of Knoop 2090 and a melting point of 3540°C. The powder is used as an abrasive and for hot pressing into heat-resistant and abrasion-resistant parts.

Z

Zirconium Diboride

Zirconium diboride (ZrB_2) has a density of 6.09 g/cm^3 and a hexagonal (AlB_2) crystal structure with a melting point of 3040°C .

Zirconium diboride is oxidation resistant at temperatures $<1000^\circ\text{C}$ and reacts slowly with nitric, hydrochloric, and hydrofluoric acids. It reacts with aqua regia and hot sulfuric acid, as well as with used alkalies, carbonates, and bisulfates. Zirconium diboride has a typical room temperature electrical resistivity of $9.2 \times 10^{-6} \Omega \cdot \text{cm}$ and is superconductive at temperatures less than 2 K. The consolidation of ZrB_2 powder into parts is accomplished by hot pressing or pressureless sintering.

Similar to titanium diboride, ZrB_2 is wet by molten metals but is not attacked by them, making it a useful material for molten metal crucibles, free-formed nozzles, electric discharge machining electrodes, Hall–Heroult cell cathodes, and Thermowell tubes for steel refining. The last use is one of the largest uses of zirconium diboride. Other uses for ZrB_2 include electrical devices, refractories, and applications where high oxidation resistance is required.

Others

Zirconium oxychloride is a cream-colored powder soluble in water that is used as a catalyst, in the manufacture of color lakes and in textile coatings. Zirconium-fused salt, used to refine aluminum and magnesium, is zirconium tetrachloride, a hygroscopic solid with 86% ZrCl_4 . Zirconium sulfate comes in fine, white, water-soluble crystals. It is used in high-temperature lubricants, as a protein precipitant, and for tanning to produce white leathers. Soluble zirconium is sodium zirconium sulfate, used for the precipitation of proteins, as a stabilizer for pigments and as an opacifier in paper. Zirconium carbonate is used in ointments for poison ivy, as the zirconium combines with the hydroxy groups of the urushiol poison and neutralizes it. Zirconium hydride has been used as a neutron moderator, although the energy moderation may be chiefly from the hydrogen.

Zincrometal

A steel coil-coated product consisting of a mixed-oxide underlayer containing zinc particles and a zinc-rich organic (epoxy) topcoat. It is weldable, formable, paintable, and compatible with commonly used adhesives. Zincrometal is used to protect outer body door panels in automobiles from corrosion.

Zone

Any group of crystal planes that are all parallel to one line, which is called the zone axis.

Zone(d) Furnace

A furnace in which the charge progresses through a number of zones where the heating rate and/or intended temperature vary. For example, the first zone might be intended to slowly preheat, the second to quickly rise to the peak temperature, and the third to allow initial cooling at some controlled rate. The zones are not normally separated by any physical barrier but have individual heating input and control systems.

Zone Leveling

A technique for homogenizing a material. It is similar to zone refining except that the heated zone sweeps back and forth repeatedly. This has the effect of redistributing impurities evenly along the length except at the extremities.

Zone Melting

(1) Highly localized melting, usually by induction heating, of a small volume of an otherwise solid metal piece, usually a metal rod. By moving the induction coil along the rod, the melted zone can be transferred from one end to the other. In a binary mixture where there is a large difference in composition on the liquidus and solidus lines, high purity can be attained by concentrating one of the constituents in the liquid as it moves along the rod. (2) Melting a narrow zone and zone leveling and zone refining.

Zone Refining

A technique for refining metals that are already nearly pure. It utilizes a local heat source, which slowly and repeatedly sweeps a narrow molten zone along a bar of the metal. In the appropriate cases where the impurity element depresses the melting point of the solvent, the molten zone collects some of the impurity and deposits it at the bar ends.

Zone Sintering

Highly localized, progressive heating during sintering to produce a desired grain structure, such as grain orientation, and directional properties without subsequent working.
